Abstract:

Investigations of the diversity of culturable yeasts at deep-sea hydrothermal sites have suggested possible interactions with endemic fauna. Samples were collected during various oceanographic cruises at the Mid-Atlantic Ridge, South Pacific Basins and East Pacific Rise. Cultures of 32 isolates, mostly associated with animals, were collected. Phylogenetic analyses of 26S rRNA gene sequences revealed that the yeasts belonged to *Ascomycota* and *Basidiomycota* phyla, with the identification of several genera: *Rhodotorula*, *Rhodosporidium*, *Candida*, *Debaryomyces* and *Cryptococcus*. Those genera are usually isolated from deep-sea environments. To our knowledge, this is the first report of yeasts associated with deep-sea hydrothermal animals.

Keywords: yeasts • hydrothermal vents • fauna • 26S rRNA gene • FISH

Introduction

Yeasts are ubiquitous microorganisms that represent a part of the microbiota in all natural ecosystems, such as soils, freshwaters and marine waters from the ocean surface to the deep sea. Marine yeasts are divided into obligate and facultative groups. Obligate marine yeasts are yeasts that have never been isolated from anywhere other than the marine environment, whereas facultative marine yeasts are also known from terrestrial habitats (Kohlmeyer & Kohlmeyer, 1979). Based on these definitions, Kohlmeyer & Kohlmeyer (1979) examined yeasts occurring in marine environments and gathered a list of 176 species isolated from diverse marine habitats. Of those, only 25 were obligate marine yeasts, widely represented by the genera Metschnikowia, Rhodosporidium, Candida and Torulopsis.

Hawksworth (2002) hypothesized the existence of 1.5 million fungal species; this estimate is now a commonly used and accepted figure. If this is correct, <5% of the fungi have been described up to now and these almost exclusively from terrestrial environments. In that ecosystem, fungi are known to utilize a wide spectrum of simple and more complex organic compounds. The decomposition activities of fungi are clearly important in relation to the redistribution of elements among organisms and environmental compartments (Gadd, 2007). Bearing in mind these parameters, our hypothesis is that deep sea and especially hydrothermal vents, which remain underexplored habitats for fungi, could be ecological niches hosting specific fungal communities.

Deep-sea hydrothermal vents are localized at seafloor spreading centers called rifts, where seawater seeps into cracked regions caused by the presence of hot basalt and magma.

1
2
3 57 Seawater carrying dissolved minerals is then emitted from springs. Two major types of
4
5 58 emissions have been found. Warm fluids diffuse at temperatures ranging from 6 to 23°C into
6
7 59 seawater at 2-4°C when hot vents called black smockers emit hydrothermal fluid at 270-
8
9 60 380°C (Munn, 2003). Thermal gradients in hydrothermal vents are so important that just a
10
11 61 few centimeters away, the temperature can fall to 2-4°C allowing mesophilic or psychrophilic
12
13 62 organisms as well as thermophilic and hyperthermophilic prokaryotes to grow and interact
14
15 63 with all biotic or abiotic components of these ecosystems. Dense animal communities cluster
16
17 64 around those hot springs. These communities are supported by the chemolithoautothrophic
18
19 65 activities of prokaryotes (Jorgensen and Boetius, 2007).
20
21 66 The occurrence of fungi (filamentous fungi and yeasts) at deep-sea hydrothermal vents
22
23 67 remains an underexplored topic. Over the last years, the interest for the diversity of microbial
24
25 68 eukaryotes in these ecosystems emerged using PCR amplification of SSU ribosomal RNA
26
27 69 genes and sequence analysis (Edgcomb *et al.* 2002; Lopez-Garcia *et al.*, 2003; 2007). These
28
29 70 papers revealed a scarce fungal diversity but some sequences were novel. Only two papers
30
31 71 have specifically dealt with fungal diversity at deep-sea hydrothermal vents based on culture-
32
33 72 dependent methods (Gadanho & Sampaio, 2005; Burgaud *et al*, 2009). Culturable yeasts
34
35 73 affiliated to *Ascomycota* and *Basidiomycota* phyla were reported from hydrothermal waters.
36
37 74 Some papers assessing fungal diversity at deep-sea vents were also published. Bass *et al.*
38
39 75 (2007) reported the presence of sequences affiliated to *Debaryomyces hansenii* and novel
40
41 76 sequences closed to *Malassezia furfur* in hydrothermal sediments. Le Calvez *et al.* (2009)
42
43 77 reported that fungal diversity from deep-sea vent animals was widely constituted of sequences
44
45 78 affiliated to *Chytridiomycota* and *Basidiomycota* phyla. The latter phylum was mostly
46
47 79 represented by yeasts with, for example, the *Cryptococcus* and *Filobasidium* genera that form
48
49 80 dense clusters.
50
51 81
52
53 82 The occurrence of yeasts in other deep-sea environments has been much more studied.
54
55 83 Nagahama *et al.* (2001b) reported that culturable fungal diversity was dominated by
56
57 84 ascomycetous yeasts in surface sediments in water depths exceeding 2000 meters (*Candida*,
58
59 85 *Debaryomyces*, *Kluyveromyces*, *Saccharomyces* and *Williopsis*). Inversely, diversity was
60
86 dominated by basidiomycetous yeasts on the subsurface of sediments in water depths
87 exceeding 2000 meters and from deep-sea clams, tubeworms and mussels (*Rhodotorula*,
88 *Sporobolomyces, Cryptococcus* and *Pseudozyma*). Recent studies have clearly demonstrated
89 that *Cryptococcus* was the dominant genus sequenced from sediments collected at deep
90 methane cold seeps (Takishita *et al.*, 2006; 2007). Those observations are in agreement with

1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60

91 Bass *et al.* (2007) who suggest that yeast forms dominate fungal diversity in deep oceans.
92 Several yeasts mostly isolated from deep-sea sediments represented new species in the
93 *Ascomycota* or *Basidiomycota* phyla (Nagahama *et al.*, 1999; 2001a; 2003a; 2003b; 2006a;
94 2008).
95
96 In this study, we decided to assess the presence of yeasts at deep-sea hydrothermal vents
97 based on a culture-based approach with an emphasis on yeasts in interactions with the
98 endemic animal fauna thriving in these extreme ecosystems. A recent paper (Gadanho and
99 Sampaio, 2005) has dealt with the diversity of yeasts in deep-sea vent waters but, to our best
100 knowledge, this is the first report of the culturable yeasts isolated from deep-sea animals.
101 Those interactions with the fauna are discussed based on the cultures obtained from the
102 samples collected during different oceanographic the cruises at Mid-Atlantic Ridge, South-
103 West Pacific Lau Basin and East Pacific Rise.

For Peer Review

104 Materials and methods

105 *Environmental sampling*

106 210 hydrothermal samples were collected during 6 oceanographic cruises at several dates and
107 locations (For hydrothermal vents locations, see Tivey, 2007): (i) BIOLAU in the Lau Basin,
108 South-west Pacific (12/05/1989–27/05/1989; 20°3.0′S, 176°7.8′W; -2620 m); (ii)
109 DIVANAUT2 (19/06/ 1994–01/07/1994) on the MAR at Menez Gwen (37°51′N, 31°31′W; -
110 900 m) and Lucky Strike (37°17′N, 32°16′W; -1650 m) hydrothermal sites; (iii) HERO on the
111 EPR at Elsa site (30/09/1991–04/11/1991; 12°48′N, 103°57′W; -2630 m); (iv) MARVEL
112 (29/08/1997–13/09/1997) on the MAR at Menez Gwen and Lucky Strike sites; (v) EXOMAR
113 (25/07/2005–28/08/2005) on the MAR at Rainbow (36°08′N, 34°00′W, -2300 m), TAG
114 (26°02′N, 44°54′W, -3630 m) and Lost City (30°04′N, 42°12′W, -900 m) sites; (vi)
115 MoMARDREAM-Naut (08/07/2007–19/07/2007) on the MAR at Rainbow site. Depending
116 on cruises, deep-sea sampling was performed using the Deep Submergence Vehicle "Nautile"
117 or the Remote Operated Vehicle (ROV) "Victor 6000" and the N/O "Atalante" and
118 "Pourquoi Pas?" research vessel.
119 The deep-sea samples were processed as described by Burgaud *et al* (2009) taking care to
120 avoid contamination in applying strict sterile sampling conditions.
121

122 *Enrichment conditions and isolation*

1
2
3 123 The samples were processed directly after the Nautile or ROV recovery. The ollected samples
4
5 124 mainly composed of deep-sea hydrothermal vent animals (*Rimicaris exoculata* and
6
7 125 *Chorocaris chacei* shrimps and *Bathymodiolus azoricus* mussels) were used to inoculate the
8
9 126 GYPS culture medium that led to the best isolation rate during a previous study (Burgaud *et*
10
11 127 *al.*, 2009). This medium contained per liter: glucose (Sigma) 1 g, yeast extract (AES) 1 g,
12
13 128 peptone (AES) 1 g, starch (Fisher) 1 g, sea salts (Sigma) 30 g. This medium was
14
15 129 supplemented per litre with agar 15 g and chloramphenicol (Sigma) 500 mg, pH was also
16
17 130 adjusted to 7.5. Cultures were done aerobically at 4°C, 15°C, 25°C (ambient temperature), 35
18
19 131 and 45°C (only during EXOMAR) at atmospheric pressure until fungal strains were
20
21 132 visualized. During the MoMARDREAM-Naut cruise, some dissections were realized on
22
23 133 board on animal samples in order to investigate the yeast location.
24
25 134 Each purified strain from our collection (Table 1) has been integrated to the 'Souchothèque de
26
27 135 Bretagne' culture collection
28
29 136 (http://www.ifremer.fr/souchotheque/internet/htdocs/generique.php?pagebody=catalogue.php
30
31 137) and are available with an accession number associated to their GenBank number.
32
33 138

34
35 139 ***Physiological characterization and statistical analysis***

36
37 140 All experiments were done in triplicate. The yeasts were grown in liquid GYPS broth media.
38
39 141 The effect of temperature on growth was determined at 5°C, 15°C, 25°C and 35°C at 30 $g.L^{-1}$
40
41 142 sea salts. The effect of salinity was analyzed modifying sea salts concentrations in media from
42
43 143 0 to 60 g.L-1 with steps of 15 g.L-1 at optimal temperature for each strain. Optical densities
44
45 144 (OD) were measured at 600 nm with Nanocolor 100D (Macherey-Nagel, Hoerdt, France) at
46
47 145 17, 22, 25 and 28 hours of growth under each condition of salinity and temperature.
48
49 146

50
51 147 ***DNA extraction and 26S rDNA sequencing***

52
53 148 DNA of each strain was extracted using FastDNA Spin Kit (MP Biomedicals, Illkirch,
54
55 149 France) specific for fungi and yeasts. Amplifications of the D1/D2 region of 26S rDNA were
56
57 150 carried out with rDNA primers ITS5 (5'-GGA AGT AAA AGT CGT AAC AAG-3'), LR6
58
59 151 (5'-CGC CAG TTC TGC TTA CC-3'), NL1 (5'-GCA TAT CAA TAA GCG GAG GAA
60
152 AAG-3') and NL4 (5'-GGT CCG TGT TTC AAG ACG G-3') as described by Gadanho &
153 Sampaio (2005). All PCR reactions were performed in 20 µL reaction volumes containing 19
154 µL of 1X PCR Buffer (Promega), 2 mM of $MgCl_2$, 0.2 mM of each dNTPs (Promega), 0.6

For Peer Review

µM of primers (forward and reverse), 1.25 U of Taq DNA Polymerase (Promega) and 1µL of DNA. The polymerase chain reactions were performed on PTC-200 (Biorad, France). The amplification consisted in an initial denaturation step at 94°C for 2 min, followed by 30 iterations of 15 sec at 94°C, 30 sec at 54°C, 1 min at 72°C and a final extension step of 2 min at 72°C. A negative control with sterile distilled water replacing DNA was added. Two kinds of amplification were generated using ITS5-NL4 and NL1-LR6 primers. The amplified DNA fragments were separated by electrophoresis in 0.8% agarose (w/v) gel (Promega) in 0.5X Tris-Borate-EDTA (TBE) Buffer at 90 V for 1h and stained with ethidium bromide. A molecular size marker was used for reference (Lambda DNA/EcoR1+Hind III Markers, Promega). The DNA banding patterns were visualized under UV transillumination and picture files were generated using Gel-Doc 2000 (Biorad, France).

The sequencing of the D1/D2 region of the 26S rDNA was then realized using NL1 on the ITS5-NL4 fragments and NL4 on the NL1-LR6 fragments. The sequences were obtained by "Big Dye Terminator" technology (Applied Biosystems). This work was done at "Biogenouest" sequencing facility in the "Station Biologique de Roscoff" (www.sb-roscoff.fr).

Phylogenetic analyses

Sequences were edited and cleaned using Sequencher v 4.8 (Gene Codes). Sequences were then imported to MEGA 4.0 software (Tamura *et al.*, 2007). Each sequence was analyzed in order to find GenBank sequences with close BLAST-N hits (Altschul *et al.*, 1990). Similarities between sequences were assessed using pairwise distance calculation with MEGA 4.0. The sequences were trimmed to ensure that all sequences had the same start and end-point. All the D1/D2 regions of the 26S rDNA sequences were aligned using ClustalW v.1.83 (Thompson *et al.*, 1994). After visual checking and manual curation, an alignment composed of 62 taxa and 579 characters was analysed for the Bayesian estimation of phylogeny using MrBayes v.3.1.2 software (Ronquist and Huelsenbeck, 2003). A two-million generation option has been set to run the Metropolis-coupled Monte Carlo Markov Chain method (*mcmc*). After generation 2 000 000, the standard deviation of split frequencies was $P = 0.005997$ indicating that a convergence had occurred (P-value of < 0.05). The alignment was analysed using MODELTEST v.3.7 (Posada and Crandall, 1998), in order to obtain the more realistic evolutionary model used for phylogenetic analyses (GTR + G model; gamma-distribution shape parameter = 0.3978). Phylogeny was then evaluated using two different

187 methods: (i) Bayesian inference with MrBayes v.3.1.2 analysis using 2 000 000 generations
188 and the *mcmc* method. The tree search included two *mcmc* searches with four chains (setting
189 default temperature for heating the chains) and a sampling frequency of 100 generations. A
190 'burnin' of 5000 (25% of the 2 000 000 generations/100 sample frequency) was set in order to
191 exclude the first 5000 trees generated. (ii) Maximum likelihood with 100 bootstrap iterations
192 using PHYML (Guindon *et al*., 2005) and the parameters obtained with MODELTEST v.3.7.
193 The final phylogenetic tree topology was realized using MrBayes v.3.1.2 analysis results.
194 Nodes in the tree show Bayesian posterior probabilities and ML bootstraps respectively.

195 ***Fluorescent probe design and evaluation***

196

197 For the detection of yeasts isolated from deep-sea vent animals by FISH, we designed
198 oligonucleotide probes using the Primrose software (http://www.bioinformatics-
199 toolkit.org/Primrose/index.html) as described by Ashelford *et al.* (2002) using a set of high-
200 quality, full-length rRNA sequences of probe target organisms. The PrimRose design tool
201 permitted to produce oligonucleotide probes for the three principal clusters of our collection
202 (Table 3). These probes exhibited no mismatches with the target organisms but exhibited
203 mismatches with the next most similar sequences in the GenBank database proving that the
204 designed probes were *in silico* highly specific. The target sites of newly designed probes were
205 checked for accessibility using the prediction maps based on the 26S rRNA of *Saccharomyces*
206 *cerevisiae* (Inacio *et al.,* 2003). Each probe was in a relative accessible area of the 26S rRNA
207 secondary structure (Fig S1). As it was not possible to test the probes with culture isolates that
208 exhibited zero or one mismatch with the probes, we used an alternative method and tested the
209 probes against all strains from our collection displaying two or more mismatches with the
210 oligonuceotides. All newly designed probes were labelled at the 5' terminus with the
211 fluorescent marker Cy3. All probes were synthesized by (Proligo, France) and stored in sterile
212 distilled water at -20°C. The newly designed probes were checked under *in situ* conditions
213 with target and non-target species. The universal probe Euk516-Fluorescein (5'-
214 ACCAGACTTGCCCTCC-3'; Amann *et al.,* 1995) and the non-Euk516-Cy3 (5'-
215 CCTCCCGTTCAGACCA-3') probes were used as positive and negative control respectively.
216 The average cell brightness was measured using different formamide concentrations from 0 to
217 80% with steps of 10%. Systematic evaluation of the signal intensities was done by recording
218 images of independent visual fields (encompassing at least 100 cells), followed by digital
219 image analysis using the daime software (Daims *et al.,* 2006). During this step, the intensities

9
10 223 *On environmental samples*. Interior branchiostegites of *Rimicaris exoculata* shrimps and
11
12 224 byssus of *Bathymodiolus azoricus* mussels were processed for FISH analyses. Following
13
14 225 harvest and dissections, animal subsamples were fixed with 4% paraformaldehyde solution in
15
16 226 phosphate-buffered saline (PBS) for 3 hours at 4°C in a dark room. After fixation, tissues
17
18 227 were washed three times with PBS and stored at -20°C in a storage buffer containing PBS and
19
20 228 96% ethanol (1:1).
21
22 229 *On membrane filters*. The seawater surrounding shrimps (MoMAR08, Rainbow) was sampled
23
24 230 in 5 L sterile sampling bags using a peristaltic pump. Immediately after dives, seawater
25
26 231 samples for *in situ* hybridizations were mixed with 3 % formaldehyde (final concentration) 2
27
28 232 hours at 4°C. Fixed seawater was then filtered on polycarbonate membranes 0.22 µm
29
30 233 (Nuclepore®, 47 mm diameter; Whatman, Maidstone, Kent, UK) and rinsed with a PBS 2X -
31
32 234 sterile seawater (v:v) buffer. Then filters were dehydrated using ethanol series (50 %, 80 %
33
34 235 and absolute, 3 min each). Dried filters were stored at -20°C until hybridization treatments.
35
36 236 Three membranes were treated in this study. The filtered volume was 0.8 L for membrane A,
37
38 237 1 L for membrane B and 1.5 L for membrane C. The filtered seawater on membranes A and B
39
40 238 was from the same sample.
41
42 239 The samples (environmental samples and membrane filters) were cut in squares and paste
43
44 240 with one drop of 0.2% low-gelling point agarose (35-40°C) on slides (Menzel-Glaser,
45
46 241 Germany). All slides were then dipped in 0.2% agarose and air dried. Samples were then
47
48 242 subjected to dehydratation with increasing concentrations of ethanol (50, 80, and 96%, for 3
49
50 243 min each). Working solutions of probes had a concentration of 30 ng of DNA per liter. The
51
52 244 hybridization buffer, containing 0.9 M NaCl, 20 mM Tris-HCl (pH 7.2), 0.03% SDS, and 0,
53
54 245 10, 20, 30, 40, 50, 60, 70 and 80% formamide, and the fluorescent probe were gently mixed
55
56 246 in a ratio of 10:1 (vol/vol) to get a final oligonucleotide concentration of 3 ng per liter. For
57
58 247 hybridization, slides were placed in sampling tubes and incubated at 46°C in the dark for
59
60 248 exactly 3 hours. Following hybridization, the slides were washed with prewarmed washing

DAPI stained (final concentration 1 µg/ml) and mounted with the antifading reagent Citifluor AF 2 (Citifluor, France) before observations under fluorescent microscope.

Results

Yeast isolation

Yeasts were not found in all the studied sites as shown in Table 1. No yeast was isolated from samples collected during HERO (on the East Pacific Rise at Elsa site), DIVANAUT2 and MARVEL (Menez-Gwenn and Lucky Strike) cruises or at TAG site during the EXOMAR oceanographic cruise. The hydrothermal site that yielded the highest number of isolates was clearly Rainbow (29 isolates out of 32 strains). Rainbow is also the site where the highest number of samples was processed (97/210). The yeast collection obtained from deep-sea samples raised thirty-two isolates that could be divided in pigmented yeasts (18) and non-pigmented yeasts (14). Pigmented yeasts consisted widely of red-pigmented yeasts (16), black-pigmented yeast (1) and brown-pigmented yeast (1).

Regarding yeast isolation versus type of substrate, strains were obtained mostly from hydrothermal shrimps *Rimicaris exoculata* (11), *Chorocaris chacei* (3), *Mirocaris fortunata* (1) and from hydrothermal mussels *Bathymodiolus azoricus* (7). Carbonate colonization modules deployed for 1 year near Rainbow vent yielded a few yeasts (4); sponges led to the isolation of three yeasts. Finally, seawater, gastropods and coral samples permitted to obtain one strain each (Table 1). Those results indicate that yeasts were much more associated with animals rather than mineral substrates. Statistical distribution tests have been performed in order to find out the distribution type of yeasts in hydrothermal sites. The variance to mean ratio (s2/m) was calculated for each site (Cancela da Fonseca, 1966). Values of s2/m significantly different of 1 corresponds with (s2/m) - 1 > 2(2n/(n - 1)2)1/2 and were obtained only for Rainbow site. For this hydrothermal site, an aggregate distribution was observed (s2/m=1.32) indicating that the culturable yeasts isolated were located in specific niches in this hydrothermal site (mainly shrimps and mussels).

During the MoMARDREAM-Naut cruise, dissections of body components were processed for all shrimps (branchiostegites, scaphognathites, exopodites, gills, stomach and digestive tract) and mussels (interior and external faces of shells) to investigate the localization of yeasts in deep-sea animals. For shrimps, a large majority of strains were grown from the inner side of the branchiostegites that can be divided in 3 different compartments: (a) an antero-

For Peer Review

ventral area, which was relatively clear; (b) a posterior area, which always remained light beige; (c) an antero-dorsal area with an intensely rusty coloration (for schematic views, see Zbinden *et al.*, 2004; Corbari *et al,* 2008). Yeast isolates resulted from this study were all cultivated from the antero-dorsal area characterized by high amounts of minerals and a dense bacterial mat.

The yeasts were also isolated from *Bathymodiolus azoricus* (7) during the MoMADREAM-Naut oceanographic cruise (Table 1). Most of them (6) were cultivated from external face of the mussel shells and more precisely from the byssus that is a network of filaments allowing attachment to rocks. This tangle gathers a lot of particles and organic matter in decomposition (personal observation). Only one yeast was isolated from the interior of a mussel (Mo32).

Physiological analysis

Three categories of strains were identified (Table 2) based on the definition of halotolerant and halophilic microorganisms (Margesin & Schinner, 2001; Kushner, 1978). Non halophiles are strains with maximal growth without sea salts and a decreasing growth rate with increased sea salts concentration in media. Halotolerant yeasts are strains able to grow in the absence as well as in the presence of salt. Halophiles required salt for an optimal growth. Regarding halophily, optimal salinities, optimal temperatures and OD measurement, 9 physiological groups were defined. Most of the isolated strains were non halophiles (23 strains) and halotolerant (2 strains, maximal OD at 30 g/l sea salts) growing efficiently at an optimal temperature of 25°C. Four strains had poor maximal growth at 25°C including 1 non halophile, 2 halotolerant (maximal OD at 30 and 60 g/l sea salts) and 1 halophile (maximal OD at 30 g/l sea salts). Three strains had maximal and efficient growth at 35°C, including 1 non halophile, 1 halotolerant (maximal OD at 45 g/l sea salts) and 1 halophile (maximal OD at 30 g/l sea salts).

Identification

For species identification, a sequence analysis of the D1/D2 domain of the 26S rRNA gene was done (Fig 1). A total of 12 phylotypes was found among the collection of yeasts isolated from deep-sea hydrothermal vents. Eleven phylotypes could be assigned to a known yeast species and one represents a new yeast species.

For Peer Review

Within *Basidiomycota*, the *Sporidiobolales* order was the dominant cluster composed of 16 strains. A majority of strains (Ex2, Ex3, Ex4, Ex5, Ex6, Ex7, Ex9, Ex11, Ex12, Mo32, Mo35 and Mo37) was identified as *Rhodotorula mucilaginosa* (100% similarity). A large majority of *R. mucilaginosa* was isolated from deep-sea shrimps (14) and the others from deep-sea mussels (2). As member of the *Sporidiobolales* order, isolates affiliated to *Rhodosporidium diobovatum* were also isolated (Mo24, Mo33 and Mo38) with 100% similarity. These 3 strains were isolated respectively from *Rimicaris exoculata* exuviae in decomposition on smocker rocks, *Bathymodiolus azoricus* and a sponge. One strain isolated from *R. exoculata* was identified as *Sporobolomyces roseus* based on 26S rRNA genes (Mo22) with 100% similarity with the reference strain. Four strains (Mo26, Mo27, Mo28 and Mo29) were affiliated to the *Filobasidiales* order and identified as *Cryptococcus uzbekistanensis* (100% similarity). These four strains were all isolated from a carbonate colonization module. Finally, one isolate (Mo36) from *B. azoricus* mussel was identified as *Leucosporidium scottii* in the *Leucosporidiales* order.

The *Ascomycota* phylum gathered 9 strains belonging to the *Saccharomycetales* order. Within this order, 4 strains (Mo20, Mo21, Mo40 and Bio2) isolated respectively from *R. exoculata*, *Mirocaris fortunata*, a deep-sea coral and the gills of the gastropod *Ifremeria nautilei* were identified as *Debaryomyces hansenii* (100% similarity). *Candida atlantica* isolates were found in *R. exoculata* exuviae in decomposition (Mo25) and *B. azoricus* (Mo31). One strain isolated from a deep-sea sponge (Ex15) was identified as *Pichia guilliermondii* (100% similarity). Finally, among the *Saccharomycetales* order, one strain was identified as *Candida viswanathii* (Bio1) with 100% similarity. One halophilic strain (Mo39) isolated from a deep-sea coral represents a new species in the *Candida* genus and thus was identified as *Candida* sp. This strain has 95% similarity with the reference sequence of *Candida atmosphaerica* (23 mismatches on 505 bp). Mo30 isolated from *Bathymodiolus azoricus* was identified as *Phaeotheca triangularis* (mitosporic *Ascomycota*) with 100% similarity. In the *Dothideales* order, one strain (Mo34) isolated from *Bathymodiolus azoricus* was identified as *Hortaea werneckii* with 99.98% similarity (one mismatch on 560bp).

Sequencing of the 26S rRNA genes indicated the presence of *Ascomycota* and *Basidiomycota* in our culture collection. In term of quantity, the phylum *Basidiomycota* (21) was two times higher than the *Ascomycota* (11). In term of species richness, ascomycetous yeasts belonged to 7 different clusters while basidiomycetous yeasts belonged to 5 clusters.

Fluorescence *in situ* hybridizations

We processed numerous assays to detect fungi on deep-sea hydrothermal vent animal samples using different existing fluorescent probes from different databases. The Euk516-Cy3 probe gave positive results on pure cultures but strong background fluorescence on hydrothermal samples led to the renouncement of its use. The probe MY1574 targeting *Eumycota* organisms (Baschien *et al.*, 2008) showed very weak fluorescence on pure cultures. Thus, we decided to design our own probes (Table 3) based on our culture collection that was divided in 3 main clusters: **MitoFilo** (*Cryptococcus* / Mitosporic *Filobasidiales* order), **MitoSporidio** (*Rhodotorula*, *Rhodosporidium* / Mitosporic *Sporidiobolales* order) and **Sacch** (*Debaryomyces*, *Pichia* / *Saccharomycetales* order). The probes designed revealed a strong specificity for the target organisms. The optimal conditions for the *in situ* hybridization protocol use stringent conditions of 20% formamide (Fig S1).

Our aim was to check the applicability of the FISH method to the *in situ* detection of yeasts in deep-sea hydrothermal fauna samples. Hydrothermal body components of endemic shrimps (*Rimicaris exoculata*) and mussels (*Bathymodiolus azoricus*) were fixed for FISH experiments directly after dissection. The pieces of shrimps and mussels that gave the higher number of fungi isolation (interior branchiostegites of shrimps and byssus of mussels) were analyzed for yeast cell fluorescence. Although shrimp and mussel samples from Rainbow site led to the highest rate of isolation, no FISH signal was ever observed. The FISH detection limit of 10^3-10^4 target cells per ml is relatively high (Daims *et al.*, 2005) and thus, the absence of FISH signals does not necessarily mean that the target organisms were not present in the samples.

To test this hypothesis, several volumes of water were concentrated on polycarbonate membrane filters to yield sufficient cells for FISH experiments with these new probes. Membrane filters were embedded in low gelling-point agarose to minimize cell loss. Yeast cells could be visualized in a low quantity on these membrane filters (Fig 2). Such results are another evidence of the yeast cells presence in hydrothermal vents but at low concentration. Using FISH on membrane filters, yeast cells detected were affiliated to 3 genera: *Rhodosporidium*, *Rhodotorula* and *Cryptococcus*.

2
3 384 ***Occurrence of yeasts in deep-sea hydrothermal vents***
4
5
6 385 In this study, the main aim was to isolate yeast strains from deep-sea hydrothermal endemic
7
8 386 fauna knowing that yeasts can be isolated from seawater surrounding hydrothermal fauna
9
10 387 (Gadanho and Sampaio, 2005). Yeast isolation was successful even if the retrieved species
11
12 388 richness was relatively low. Thirty-two strains were isolated mostly from *Rimicaris exoculata*
13
14 389 shrimps. The association with shrimps is probably favorable for yeasts that could benefit from
15
16 390 nutrients due to the water circulation in the gill chamber. Most of our strains were isolated
17
18 391 from the Rainbow hydrothermal site which confirms previous results (Gadanho and Sampaio,
19
20 392 2005). The Rainbow hydrothermal field hosted in ultramafic rocks is a unique vent enriched
21
22 393 in CH_4, H_2, CO, Fe and depleted in H_2S (Charlou *et al*., 2002). The high yeast isolation ratio
23
24 394 may indicate that yeasts thrive in hydrothermal sites depleted in H_2S. The isolation rate of
25
26 395 non-pigmented yeasts on sulfur-free media significantly higher than those on sulfur-based
27
28 396 media in a previous study (Gadanho & Sampaio, 2005) support such hypothesis.
29
30 397
31
32 398 Several yeasts were also isolated from mussels and more precisely from the byssus
33
34 399 constituted of filaments with a high concentration of minerals and organic matter. These
35
36 400 yeasts may have a role in the decomposition of organic material entrapped in mussel byssi in
37
38 401 deep-sea vents. These results seem promising as they confirm the data obtained in previous
39
40 402 studies and suggest that yeasts may interact with deep-sea hydrothermal vent fauna.
41
42 403
43
44 404 ***Pattern of the culturable yeast communities***
45
46 405 *New species.*
47
48 406 The yeast that was firstly isolated from stomach of a marine fish was described as *D. hansenii*
49
50 407 and deposited in the Centraalbureau voor Schimmelcultures (CBS 5307) database. In a recent
51
52 408 paper, based on the intergenic spacer (IGS) region of the rRNA gene, this strain was re-
53
54 409 evaluated as *Candida sp.* (Nguyen *et al.*, 2009). This strain is identical to another one isolated
55
56 410 from deep-sea hydrothermal vent waters and annotated MARY089 (Gadanho and Sampaio,
57
58 411 2005). These two strains isolated from different marine environments were finally reported as
59
60 412 a single new undescribed species within the *Candida* genus. In our collection, strain Mo39,

413 isolated from deep-sea coral near Rainbow hydrothermal vents (Table 1), has the same 26S

414 rRNA gene sequence as CBS 5307 and MARY089. Mo39 is halophilic and thus supposed to

415 be an autochtonous marine yeast species. This new ecotype can be characterized as an

416 obligate marine yeast and its complete description is currently under progress.

For Peer Review

Known species

Two strains (Mo25 and Mo31) isolated from *Rimicaris exoculata* and *Bathymodiolus azoricus* samples were identified as *Candida atlantica*. This result seems in keeping with previous published reports that have isolated this species from coastal seawater in the South of Portugal (Gadanho *et al.*, 2003) and in deep-sea hydrothermal vent waters (Gadanho and Sampaio, 2005). The very fisrt *C. atlantica* strain was isolated from shrimp eggs in the North Atlantic Ocean (Siepmann and Höhnk, 1962). *C. atlantica* seemed to be a marine obligate yeast and some interactions with shrimps seemed to occur. Our physiological analysis has revealed that Mo25 and Mo31 were non-halophiles, which does not mean that they are unable to grow in marine environments. They may have a role in deep-sea environments in interaction with endemic crustaceans even if they are not in optimal growth conditions. One isolate (Bio1) isolated from seawater surrounding mussels at Lau Basin in the South-West Pacific was clearly identified as *Candida viswanathii*. Kohlmeyer & Kohlmeyer (1979) characterized this yeast as marine facultative. More recently, *C. viswanathii* was isolated from a shrimp (*Peneaus braziliensis*) in the Gulf of Mexico. Its synonym, *Candida lodderae* was recently reported in deep-sea hydrothermal vent waters at Rainbow site (Gadanho and Sampaio, 2005) and characterized as the most abundant yeast.

Leucosporidium scottii isolates (Mo36) were retrieved only in the oceanic regions close to Antarctica and are known to be psychrophilic and probably autochthonous marine species (Lachance and Starmer, 1998). Such strains known for their presence in cold polar marine environments could be another evidence that confirms the hypothesis of global exchanges from polar environments to deep-sea vents based on results from bacteria (Maruyama *et al.*, 2000) and filamentous fungi (Burgaud *et al.*, 2009). *Hortaea werneckii* (Mo34) was characterized as halophilic in our physiological study. This is not surprising as this black yeast-like fungus was characterized as halophilic or extremely halotolerant in different studies (Gunde-Cimerman *et al.*, 2000; Kogej *et al*, 2005) where it was frequently isolated from hypersaline waters of solar salterns. In a molecular survey, *H. werneckii* was identified (based on internal transcribed spacers and 5.8 S rRNA gene) in deep-sea methane seep sediments at a depth of 2965 meters (Lai *et al.*, 2007). *Phaeotheca triangularis* (Mo30) was also frequently isolated from salted environments (Gunde-Cimerman *et al.*, 2000) and characterized as halophile. This confirmed previous results on *P. triangularis* showing a better growth with 5% additional salts (Zalar *et al.*, 1999). In our study, Mo30 was characterized as halotolerant

For Peer Review

with 4.5% sea salts optimal concentration and thus hypothesized as marine adapted yeast. This is the first report about the presence of *Phaeotheca triangularis* at deep-sea vents.
Mo22 is described as *Sporobolomyces roseus*. The genus *Sporobolomyces* is composed of strains mainly isolated from the pyllophane (Bai *et al.*, 2002). However, a previous study has proved that strains of the genus *Sporobolomyces* are frequently isolated from marine ecosystems and the frequency of isolation increases when distance from the coastline and depth increase (Hernandez-Saavedra *et al,* 1992). Moreover, yeasts from this genus were found in benthic invertebrates collected from deep-sea floor in the Pacific Ocean (Nagahama *et al*, 2001b). Our strain was isolated from a deep-sea hydrothermal shrimp in the Atlantic Ocean and characterized as halotolerant with an optimal salinity of 6% sea salts. This may indicate that yeasts of this genus are also able to live in deep-sea vents and interact with endemic crustaceans.

A previous study of yeasts in oceanic environments (Fell, 1976) reported that yeast communities appeared to be constituted of ubiquitous and endemic species. Typical ubiquitous strains were the ascomycetous yeast *Debaryomyces hansenii* and the basidiomycetous ones *Cryptococcus* and *Rhodotorula*. Kohlmeyer and Kohlmeyer (1979) confirmed this statement and characterized these genera mainly as facultative marine yeasts. Some of these results, especially for *Rhodotorula* yeasts showing a strong ubiquity, were confirmed based on their presence in several habitats such as deep-sea vents (Gadanho and Sampaio, 2005), deep-sea sediments (Nagahama *et al.*, 2001b), coastal waters (Gadanho *et al.*, 2003; 2004) and oligotrophic lakes (Libkind *et al.*, 2003). Our results confirm their ubiquity and indicate that these strains seem to be allochtonous. Strain Ex15 identified as *Pichia guilliermondii* has also been characterized as non halophile and may be another allochtonous yeast strain as reported by Kohlmeyer and Kohlmeyer (1979).

The members of the genus *Rhodosporidum* have been characterized as non halophiles (Mo24 and Mo33) and halotolerant (Mo38). Based on previous reports, this genus seemed to be restricted to marine environments (Gadanho and Sampaio, 2005). *R. diobovatum* in deep-sea vents seemed to be able to colonize different substrates (shrimps, mussels and sponges). The isolation of a strain from shrimp exuviae in decomposition may indicate a role as a recycler of organic material and so a probable implication in carbon cycle in deep-sea environments.

Adaptation to marine conditions

For Peer Review

The isolation of culturable yeasts led to an old question about marine yeasts "Are there any indigenous marine yeasts ?" (Kohlmeyer & Kohlmeyer, 1979) and to the resulting question "Which are the indigenous species ?". Based on our results, one can suggest that halophilic strains are marine indigenous yeasts and that others, halotolerant and non-halophiles, are ubiquitous terrestrial strains present in deep-sea waters due to sedimentation or other natural or anthropogenic phenomena. But almost all yeast species can grow well in media with NaCl concentrations exceeding those normally present in the sea (Kohlmeyer & Kohlmeyer, 1979). Few yeast species with a physiological dependence on NaCl or other seawater components have been reported (Nagahama, 2006b). Thus, our results appeared in good agreement with such statements. Only 2 strains described as halophiles (Mo34 and Mo39) in our study can be described as obligate marine yeasts.

FISH observations

FISH using labeled oligonucleotide probes targeting rRNA has been used as a powerful technique for assessing both microbial identity and spatial distributions *in situ* in complex environmental contexts (Yang *et al.,* 2008). Our results indicate a very low-level of yeasts at deep-sea vents. As a first conclusion, regarding diversity and quantification (added to previous results of Gadanho and Sampaio, 2005), it seems that yeasts at deep-sea vents represent a minor community that might not be major actors in biogeochemical cycles. However, fluorescent signals are correlated to the cellular content of ribosomes and consequently to the microbial growth rates. Recently, the detection limits of conventional FISH with Cy3-labeled probe EUB338 were found to be approximately 370 16S rRNA molecules per cell for *Escherichia coli* hybridized on glass microscope slides and 1,400 16S rRNA copies per *E. coli* cell in environmental samples (Hoshino *et al.,* 2008). So, in addition to a low concentration of yeast cells, low detection of yeasts may be caused by low ribosome content of most yeasts in the deep-sea environment due to low-level metabolic activities of yeasts living under extreme environmental abiotic factors (high hydrostatic pressure, low temperatures,…). Our attempts to cultivate the yeast strains resulted from this study under elevated hydrostatic pressure have been successful, but ribosomal activities were lower under high hydrostatic pressure than at atmospheric pressure. Such results may account for the low fungal detection using FISH (unpublished data). Consequently, care must be taken when dealing with diversity and biomass estimations when using FISH alone.

For Peer Review

1
2
3 517 The quantification of yeasts using FISH has been impossible due to a non homogeneous
4
5 518 repartition of microorganisms on filters. Moreover, bacterial and yeast cells were only visible
6
7 519 in some regions of the filters without minerals due to strong autofluorescence. However we
8
9 520 can say that yeast concentrations are really low, as shown by the only few cells visualized
10 521 after filtration of seawater surrounding shrimps. This result is in keeping with the relatively
11
12 522 low diversity revealed by Gadanho and Sampaio (2005) ranging from 0 to 10 cfu/L for pink
13
14 523 yeasts and from 0 to 6000 cfu/L for non-pigmented yeasts. To better analyze the fungal
15
16 524 presence in deep-sea animals, one could work with phylum-specific probes on histological
17
18 525 sections of animals and use the CARD-FISH (Amann & Fuchs, 2008) or the DOPE-FISH
19 526 (Stoecker *et al.,* 2010) methods to amplify probe signals.
20
21
22 527 These data raise emerging questions regarding the ecological role of such microorganisms in
23
24 528 deep-sea vents and about the old question of the ubiquity or endemism of those strains. Yeasts
25
26 529 at deep-sea vents may be facultative parasites or opportunistic pathogens of endemic deep-sea
27
28 530 animals as it has already been hypothesized in previous works (Van Dover *et al.*, 2007;
29
30 531 Burgaud *et al*, 2009). However, a role in th edecomposition of abundant organic material may
31 532 occur.
32
33 533 Considering all the results obtained, we can say that yeasts may seem to interact with deep-
34
35 534 sea hydrothermal endemic fauna even if the density is low. These yeasts are mainly composed
36
37 535 of ubiquitous species but obligate marine yeasts have also been harvested. However, the
38
39 536 results obtained using *in situ* hybridization have allowed us to visualize these ubiquist species
40
41 537 showing that they are able to live and grow in deep-sea hydrothermal vents. Yeasts associated
42
43 538 with endemic animals in deep-sea vents may be exposed to favorable conditions and could
44
45 539 benefit from a stable source of nutrients (Nagahama *et al.*, 2001b). Yeasts were reported from
46 540 dead and healthy individuals which may also indicate their facultative saprophytism and so
47
48 541 emphasize the wide role of fungi in the decomposition of organic matter from terrestrial
49
50 542 environments to deep-sea hydrothermal vents. Even if yeasts were isolated from animal body
51
52 543 components, they were not visualized using FISH. To better understand the interaction with
53 544 animals and fungi in deep-sea vents, we need to work on tissues as in Van Dover *et al.* (2007)
54
55 545 and also with probes specific to fungal phyla (*Ascomycota*, *Basidiomycota* and
56
57 546 *Chytridiomycota*). In conclusion, several questions regarding the role of yeasts in deep-sea
58
59 547 hydrothermal vents and the endemism or ubiquity of the isolated yeasts remain a difficult task
60 548 without clear answers. Their culture under high hydrostatic pressures would be an interesting
549 study to better characterize their lifestyle and role at deep-sea vents.

Figure 1: Phylogenetic tree of deep-sea yeast isolates (coloured terminals) and close relatives obtained by analysis of the D1/D2 domain of the 26S rRNA gene. Topology was built using MrBayes v.3.1.2 from a ClustalW 1.83 alignment. Node support values are given in the following order: MrBayes posterior probabilities/PHYML 100 bootstraps. Black squares represent nodes supported by an excess of 0.95 posterior probabilities and 95% bootstraps. *Mucor flavus* (EU071390) belonging to the *Zygomycota* phylum was used as outgroup. All sequences are listed with their GenBank accession numbers.

Figure S1 : Target sites of the fluorescent oligonucleotide probes designed on a model of the *Saccharomyces cerevisiae* 26S rRNA secondary structure in which the D1 and D2 domains (delimited by NL1 and NL4) are enlarged (Inacio *et al.,* 2003). Each probe was evaluated without formamide in order to check wether the probe binds to the ribosomes of the target cells. The optimal hybridization conditions were determined in a serie of FISH experiments with increasing formamide concentrations for a probe target and a non-target organism : (i) Sacch probe, *Debaryomyces hansenii* (Target) and *Candida atlantica* (Non-Target) with two mismatches ; (ii) MitoSporidio probe, *Rhodosporidium diobovatum* (Target) and *Cryptococcus uzbekistanensis* (Non-Target) with five mismatches and (iii) MitoFilo probe, *Cryptococcus uzbekistanensis* (Target) and *Rhodosporidium diobovatum* (Non-Target) with seven mismatches. Relative probe accessibility was determined for each probe : MitoFilo, about 60%; MitoSporidio and Sacch, 44 to 66%.
