Abstract :

A new benthic dinoflagellate species, *Prorocentrum bimaculatum* sp. nov., is studied from Kuwait's marine sediments, based on detailed morphological and molecular data. Cells are large, oblong oval in shape. They are 49.9–55.3 µm long and 38.4–43.2 µm wide. The ornamentation of this new species is peculiar, and characterized by smooth valves with large pores (0.32–0.50 µm) scattered on their surface, except in two circular patches of ~15 µm in diameter, devoid of ornamentation and located on both sides of the valve centers. The periflagellar area is widely triangular, located in a moderate excavation of the right valve, and comprises nine platelets. The intercalary band of *P. bimaculatum* is smooth. The molecular phylogenetic position of this new taxon was inferred from SSU and LSU rDNA genes. In both phylogenetic analyses, *P. bimaculatum* branched with high support with *Prorocentrum consutum* and formed a clade sister to the one including *P. lima* and related species such as *P. arenarium*, *P. belizeanum*, *P. hoffmannianum*, and *P. maculosum*. From the phylogenetic study, since most species related to *P. bimaculatum* are known for their toxic effects and production of okadaic acid, this new species can be considered as a potential toxin producer, but this has to be analyzed.

Keywords : Arabian Gulf ; benthic dinoflagellates ; Kuwait ; molecular phylogeny ; morphology, nuclear DNA ; Prorocentrum ; rDNA ; SEM ; taxonomy

Abbreviations: bp, base pairs ; ML, maximum likelihood ; MP, maximum parsimony ; BI, Bayesian inference

40 **Introduction**

41 Members of the genus *Prorocentrum* Ehrenberg constitute a diverse group of marine
42 microalgae with a wide geographical distribution and can contribute a considerable part to
43 benthic dinoflagellate assemblages, especially in sub-tropical and tropical areas (e.g. Faust
44 1990, Faust 1993a, Faust 1993b, Faust 1994, Faust and Gullede 2002, Mohammad-Noor et
45 al. 2007b). Many *Prorocentrum* species have been found to produce okadaic acid and can
46 cause diarrhetic shellfish poisoning (DSP) (Faust and Gullede 2002).

47 Studies of marine microalgae in Kuwait's marine environment were focused more on
48 the diversity of plankton community than on the composition of benthic species. The diversity
49 of benthic dinoflagellates of Kuwait has been recently reported (Saburova et al. 2009, Al-
50 Yamani and Saburova 2010a, b, Polikarpov et al. 2010) and 58 dinoflagellate taxa were
51 documented during these investigations. Members of the genus *Prorocentrum* were among
52 the most diverse thecate dinoflagellates in this environment. Eight benthic *Prorocentrum*
53 species recorded from Kuwait to date are *P. arenarium* Faust, *P. concavum* Fukuyo, *P.*
54 *consutum* Chomérat et Nézan, *P. emarginatum* Fukuyo, *P. fukuyoi* Murray et Nagahama, *P.*
55 *lima* (Ehrenberg) Stein, *P. norrisianum* Faust et Morton, and *P. rhathymum* Loeblich III et al.
56 Among them, five species can be considered as potentially toxic. The cosmopolitan species *P.*
57 *fukuyoi* is widely distributed throughout Kuwait's intertidal sandflats, and it may be the most
58 abundantly occurring species of all thecate dinoflagellates. Recently described from temperate
59 area (Chomérat et al. 2010), *P. consutum* was found to co-occur with *P. fukuyoi* in sub-
60 tropical Kuwait's intertidal sediments, but at a low abundance.

61 During the course of our studies on the populations of *P. consutum* from Kuwait's
62 intertidal sediments, we found a *Prorocentrum* species with a very characteristic morphology.
63 It was rather similar to *P. consutum* in size and shape, but it differed in the original pattern of
64 valve pores from not only *P. consutum* but also from all other currently described

65 *Prorocentrum* species. Thus, the aim of this paper is to describe this new species on the basis
66 of light and scanning electron microscopical observations and molecular phylogenetic data.

67

68 **Material and Methods**

69 *Sampling*

70 Kuwait's marine environment is generally shallow with broad flats to the north and a gentle to
71 steep shelf slope along the southern coastline. Height differences of Kuwait's mixed, semi-
72 diurnal tides from low-low water to high-high water are 3.5 to 4 m, and horizontal distances
73 between extreme tidal heights may exceed 8 km in Kuwait Bay. Mean annual temperature of
74 Kuwait's surface water is 23.8°C, with maximum in July and August, when it ranges from
75 30.5°C up to 36°C in shallow waters of Kuwait Bay; temperature minimum coincides with
76 January and February (14°C, down to 11.9°C). The mean annual salinity of this area of the
77 Arabian Gulf is 41.6 psu (Al-Yamani et al. 2004).

78 The extended seashore of Kuwait is primarily composed of expansive intertidal flats,
79 which range gradually from mud and sandy mud in the north to medium- or coarse-grained
80 and organically depleted sediments along the southern part of Kuwait's coast. Study of
81 benthic dinoflagellates was undertaken throughout Kuwait's coast from the southern part of
82 Kuwait Bay up to the Saudi border on the south, however, dinoflagellate assemblages with
83 presence of *P. bimaiculatum* were recorded only from two sampling sites (Fig. 1) in May-June
84 2010. Site 1 is a small town beach, which is located just outside Kuwait Bay (29°20'26"N,
85 48°05'49"E). Intertidal sediments are composed of rather fine sands with less content of
86 organic matter. Site 2 is located at the southern coast of Kuwait (28°46'58"N, 48°17'40"E).
87 Rather slopping intertidal sandflat is composed of medium- to large-grained and organically
88 depleted sediments.

89 Intertidal sediments were collected by sampling the upper sediment layer (0-2 cm)
90 from sandy flats, which were exposed at low tide at different intertidal heights using plastic
91 tube corers or flat spoon. The collected samples were transported directly to the laboratory,
92 where dinoflagellates were separated from the sandy sediment by extraction using the frozen
93 seawater method (Uhlrig 1964), with a 110 μm mesh size. A part of living material was
94 preliminary observed with a Leica DMIL inverted microscope (Leica, Wetzlar, Germany) at
95 $\times 35$ to $\times 200$ magnifications while a subsample was preserved with 4% neutral Lugol's
96 solution and used for further examinations and molecular analyses.

97

98 *Light and scanning electron microscopy*

99 Living cells were observed and photographed using a Leica DMLM (Leica, Wetzlar,
100 Germany) microscope fitted with a Leica DFC 320 digital camera. For detailed observations,
101 individual cells fixed in Lugol's solution were isolated from field samples and washed in
102 distilled water using a micropipette under an Olympus IX51 (Olympus, Tokyo, Japan)
103 inverted microscope. Fixed cells were examined in light microscopy with an Olympus BX51
104 upright microscope equipped with epifluorescence (100W short arc mercury lamp), Nomarski
105 Differential Interference Contrast (DIC) optics and a DP72 digital camera (Olympus). To
106 visualize nuclei, cells were stained for 30 min with 4',6-diamidino-2-phenylindole,
107 dihydrochloride (DAPI, Sigma) fluorochrome (final stain concentration $0.05 \mu\text{g ml}^{-1}$) and
108 observed in epifluorescence using an Olympus U-MWU2 fluorescence cube (330–385 nm
109 band pass excitation filter, 400 nm dichromatic beam splitter and 420 nm barrier emission
110 filter).

111 For scanning electron microscopy (SEM), cells were individually isolated and
112 concentrated in 0.2 ml tubes containing distilled water and a drop of formaldehyde to prevent
113 fungal development. Cells were filtered using polycarbonate membrane filters (Millipore

114 GTTP Isopore, 0.22 mm pore size), rinsed in deionized water and prepared according to
115 Chomérat and Couté (2008). The examination was performed with a Quanta 200 (FEI,
116 Eindhoven, the Netherlands) scanning electron microscope with an electron acceleration of 5
117 kV.

118 Cell dimensions were measured on 8 specimens: one specimen was measured in LM
119 using a calibrated micrometer on the eyepiece, while SEM digital micrographs of seven
120 specimens were processed with ImageJ software (Rasband 1997–2006). SEM photographs
121 were presented on a dark gray background using Adobe Photoshop CS2, v. 9.0.2 (Adobe
122 Systems, San Jose, CA, USA).

123

124 *DNA amplification and sequencing*

125 After their identification in LM, single cells were isolated from a field sample collected in
126 May 2010 at Site 1 using a micropipette, under an IX51 inverted microscope and transferred
127 onto a glass slide. Each cell was rinsed individually in several drops of double distilled water
128 and then transferred to 0.2 ml PCR tube containing 5 μ l of ddH₂O. Then, PCR tubes were
129 stored at –20 °C. For PCR, the samples were thawed and 25 pmol of each primer and 12.5 μ l
130 of PCR Master Mix 2X (Promega, Madison, WI, USA) containing the *Taq* DNA polymerase,
131 dNTPs, MgCl₂ and reaction buffers, were added in each tube. Two rounds of PCR were
132 realized and 1 μ l of the dilution (1/100 in ddH₂O) of the PCR product was used as a DNA
133 template for the second round of PCR. Almost the full length of the SSU rDNA (\approx 1800 base
134 pairs) was acquired for isolated cells of *P. bimaculatum* and also *P. consutum* from the same
135 sample.

136 The polymerase chain reactions for both rounds were performed in a TProfessional
137 Basic thermocycler (Biometra GmbH, Goettingen, Germany) as follows: one initial
138 denaturing step at 94 °C for 2 min, followed by 45 cycles each consisting of 94 °C for 30

139 sec, 54 °C for 30 sec, and 72 °C for 4 min, and a final elongation of 72 °C for 5 min. The PCR
140 products were purified using the Wizard SV Gel and PCR Clean-up system (Promega)
141 according to the manufacturer's recommendations. The sequencing reaction was realized
142 using the ABI PRISM BigDye Terminator Cycle Sequencing Kit (Applied Biosystems,
143 Carlsbad, CA, USA) and the sequences were determined using an automated 3130 genetic
144 analyser (Applied Biosystems).

145

146 *Sequences alignment and phylogenetic analyses*

147 The SSU and LSU rDNA sequences obtained were aligned with other putative *Prorocentrum*
148 species and two outgroup (*Scrippsiella* spp.) sequences using MUSCLE algorithm (Edgar
149 2004) followed by refinement by eye with MEGA software (Tamura et al. 2007), version 4.
150 Genbank accession numbers of all sequences used are available in the supplementary material
151 (Appendix S1).

152 Evolutionary models were examined for each data set using maximum likelihood
153 (ML), Bayesian inference analysis (BI) and maximum parsimony (MP). The evolutionary
154 model and parameters were selected using jModelTest version 0.1.1 (Posada 2008).
155 According to Akaike information criterion (AIC) and Bayesian information criterion (BIC), a
156 general time reversible (GTR) model with a gamma correction (Γ) for among-site rate
157 variation and invariant sites was chosen for the SSU dataset while a Tamura-Nei (TN93)
158 model with no invariant sites was chosen for the LSU dataset.

159 Maximum likelihood analyses were performed using PhyML version 3.0 (Guindon
160 and Gascuel 2003), Bayesian analyses were run using Mr Bayes version 3.1.2 (Ronquist and
161 Huelsenbeck 2003) and parsimony analyses with heuristic search were performed using
162 PAUP* version 4.0b for Windows (Swofford 2002). Bootstrap analysis (1000
163 pseudoreplicates) was used (for ML and MP) to assess the relative robustness of branches

164 (Felsenstein 1985). Initial Bayesian analyses were run with a GTR model (nst=6) with rates
165 set to invgamma (gamma for LSU dataset). Each analysis was performed using four Markov
166 chains (MCMC), with two millions cycles for each chain. Trees were saved every 100 cycles
167 and the first 2000 trees were discarded. Therefore, a majority-rule consensus tree was created
168 from the remaining 18000 trees in order to examine the posterior probabilities of each clade.

169 The consensus trees were edited using MEGA 4 software. The two *Scrippsiella*
170 species were used to root the trees. The best ML phylograms are shown with robustness
171 values for each node (ML/BI/MP).

172

173 **Results**

174 *Observations*

175 ***Prorocentrum bimaculatum* Chomérat et Saburova sp. nov.** (Figs 2–21)

176 *Descriptio: Organismus unicellularis, photosyntheticus et ovalis. Longitudo: 49.9–55.3 μm;*
177 *latitudo: 38.4–43.2 μm. Nucleus in medio-posteriori parte locatus et castaneae similis.*
178 *Valvae laeves cum poris dispersis praeter in duabus circularibus regionibus cum 15 μm*
179 *diametro utrinque valvae centro locatis. Pori marginales in continuo annulo dispositi in*
180 *duabus valvis. Pori diameter: 0.32–0.50 μm. Valva recta indentata in apice; valva sinistra*
181 *cum brevi apicali crista. Regio periflagellaris cum novem parvis lamellis constituta; aliquae*
182 *parvae lamellae utraeque ex parte tectae et conspicuae solum ex parte. Porus flagellaris*
183 *ovalis. Accessorius porus ovalis sed in apicale visu dissimulatus. Fascia intercalaris laevis.*

184

185 Unicellular and photosynthetic organism, oval in shape. Length: 49.9–55.3 μm; width: 38.4–
186 43.2 μm. Nucleus roughly chestnut-shaped, located in medio-posterior part of the cell. Valves
187 smooth with scattered pores, except in two circular areas of 15 μm in diameter, located on
188 both sides of the valves centre. Marginal pores present on both valves. Pore size: 0.32–0.50

189 μm . Right valve with a moderate excavation at the apex; left valve with a short apical ridge.
190 Periflagellar area composed of nine platelets; some platelets overlapping others and being
191 only partially visible. Flagellar pore oval. Accessory pore oval but hidden in apical view.
192 Intercalary band smooth.

193

194 *Habitat*: marine and benthic

195 *Holotype*: Figs 8, 10, 11, SEM stub CEDiT2010H6 stored at the CEDiT (Centre of
196 Excellence for Dinophyte Taxonomy) dinoflagellate type collection, Wilhelmshaven,
197 Germany.

198 *Isotypes*: Figs 9, 11, 15. (SEM stub CEDiT2010I7).

199 *Type locality*: intertidal sand of the town beach (site 1, 29°20'26"N, 48°05'49"E), Ras Salmiya,
200 Kuwait.

201 *Known distribution*: *P. bimaculatum* was collected from Kuwait's intertidal sediments.

202 *Etymology*: From Latin, *bis*, two and *maculatus*, spotted, in reference to the two circular areas
203 without ornamentation, like two round patches on the valves.

204

205 The cells are large, 49.9–55.3 μm long (mean 52.5, SD 2.1, $n = 8$) and 38.4–43.2 μm wide
206 (mean 40.9, SD 1.9, $n = 8$) in valve view. They are oblong oval, with a length to width ratio
207 ranging from 1.25 to 1.32 (Figs 2–9, 18–19), and flattened (*ca.* 22 μm broad in sagittal
208 suture/intercalary band view). In valve view, the anterior end of the right valve is indented
209 and has a wide V-shaped depression while the left valve forms a slight depression at the apex
210 (Figs 2–3, 6–9, 18–19). The valves are flat to slightly concave in their centre (Fig. 10). The
211 valve surface is smooth with large pores or deep depressions (0.32–0.50 μm in diameter)
212 scattered. A continuous ring of marginal pores runs alongside the periphery of valves (Figs 8–
213 12). The pores form a characteristic pattern on the right and left valves. Two large circular

214 areas (*ca.* 15 μm in diameter) are devoid of pores, on both sides of the center of each valve
215 (Figs 6–7, 8–9, 11, 16, 18–19). This characteristic has been chosen to name the species, since
216 the valves appear to possess two unornamented patches on their surface. The inside valve
217 surface is smooth, and many pores seem to be grouped by two (Fig. 15), which was not seen
218 in the external view. The intercalary band is smooth (Fig. 12).

219 The periflagellar area is widely triangular, about 8 μm long and 4.5 μm high, and
220 located in a moderate excavation of the right valve (Figs 8, 11, 13). In apical view, this area is
221 complex and comprises several platelets but some are obscured from view because of the
222 extensions formed by some platelets (Fig. 13). Consequently, only the flagellar pore is
223 partially visible (Fig. 13). Thanks to the observation of the periflagellar area from the inside
224 of a right valve, nine platelets have been identified and named according to Taylor's scheme
225 (Taylor 1980) (Fig. 14). Four platelets "a₁", "d", "f", and "h" border the small apical ridge
226 formed by the left valve (Figs 13, 20), while three other platelets "a₂", "e" and "g" are located
227 on the end of the V-shape (Figs 13–14, 20–21). The flagellar pore is surrounded by the
228 platelets "c", "f", "g" and "e" (Figs 14, 21). It is oval and measures about 1.9 μm in length
229 and 1.2 μm in width (Fig. 14). The accessory pore is totally hidden in apical view because of
230 extensions of the platelets "a₁", "a₂" and "d", but it is present and clearly visible in the internal
231 view (Fig. 14). It is oval, 1.1 μm long and 0.7 μm wide (Fig. 14). The platelet "b" and the
232 major part of "c", which is the unique platelet separating the flagellar and accessory pores, are
233 hidden in the apical view but seen in the view from the inside (Fig. 14). The platelets visible
234 apically are ornamented with deep depressions (Fig. 13).

235 Interestingly, on a probably recently-divided cell with a thin theca (Fig. 16), two kinds
236 of pores are observed in the valve center, between the two round patches (Fig. 17). The large
237 pores have the same size than those observed in older cells, and the small pores are 0.14–0.17
238 μm (Fig. 17).

239 On living cells, the nucleus is difficult to observe because of the granulated cell
240 content (Figs 2–3). On fixed specimens, it is obscured because of the coloration resulting
241 from the fixation by Lugol's solution (Fig. 4). After DAPI-staining and observation in
242 epifluorescence microscopy, the nucleus appears to be roughly chestnut-shaped, and located
243 posteriorly below the centre of the cell (Fig. 5).

244 *Prorocentrum bimaculatum* was found in Kuwait's sediments, in association with
245 other *Prorocentrum* species such as *P. fukuyoi* and *P. consutum* but at a very low abundance.

246

247 *Sequence analysis and molecular phylogeny*

248 Five identical sequences of SSU rDNA (1789 bp) were acquired from independent cells of *P.*
249 *bimaculatum* and two identical sequences were obtained for LSU rDNA (974 bp),
250 corresponding to the D1–D3 domains. In addition, two identical sequences of SSU rDNA
251 were acquired from two isolated cells of *P. consutum* to ensure the identification of this
252 species.

253 The phylogenetic trees inferred from SSU and LSU rDNA showed the existence of
254 two major lineages in the genus *Prorocentrum* identified as clade 1 and clade 2 in the
255 phylograms (Fig. 22). The clade 1 comprised asymmetric species, or those with a variable
256 morphology, including *P. dentatum* Stein, *P. donghaiense* Lu, *P. emarginatum*, *P. fukuyoi*, *P.*
257 *glenanicum* Chomérat et Nézan, *P. gracile* Schütt, *P. mexicanum* Osorio–Tafall, *P. micans*
258 Ehrenberg, *P. minimum* (Pavillard) Schiller, *P. panamense* Grzebyk et al., *P.*
259 *pseudopanamense* Chomérat et Nézan, *P. triestinum* Schiller, *P. tsawwassenense* Hoppenrath
260 et Leander and *P. rhathymum* (Fig. 22). The new species *P. bimaculatum* was included in
261 clade 2 which comprised the symmetric species *P. arenarium*, *P. belizeanum* Faust, *P.*
262 *consutum*, *P. concavum* (including the synonym *P. arabianum*), *P. faustiae* Morton, *P.*

263 *hoffmannianum* Faust, *P. levis* Faust et al., *P. lima*, *P. maculosum* Faust and unidentified
264 species “FL3” and “RAV2” (Fig. 22).

265 The SSU sequence of *P. consutum* from Kuwait grouped with a high statistical support
266 with the sequence from Brittany. The branches of nearly equal lengths indicated that they
267 hardly differ and that they unambiguously belong to the same taxon (Fig. 22A). In
268 phylogenies inferred from the two ribosomal genes, *Prorocentrum bimaculatum* formed a
269 sister-clade to that of *P. consutum*. In the SSU rDNA phylogeny, this position was supported
270 with a high posterior probability (BI) but with weaker values in ML and MP (Fig. 22A) which
271 contrasts with in the LSU phylogeny where it was fully supported (Fig. 22B). Considered
272 together, *P. consutum* and *P. bimaculatum* formed a sister group to the subclade containing *P.*
273 *lima* and related species, including *P. arenarium*, *P. belizeanum* and *P. hoffmannianum*. In the
274 LSU phylogeny, this position was fully supported with bootstraps values of 100 (ML and MP)
275 and a posterior probability of 1.00 (BI), whereas the support was weaker in the SSU
276 phylogeny as only the posterior probability was 1.00 (Fig. 22).

277

278 **Discussion**

279 In this study, we examined morphological and molecular genetic characters of *P.*
280 *bimaculatum*, a large and peculiar *Prorocentrum* species found in Kuwait’s intertidal
281 sediments. Both morphological and molecular data prove unambiguously that it corresponds
282 to a new taxon. Morphologically, its ornamentation is very peculiar, with two circular areas
283 devoid of pores on each valve. Several species are devoid of ornamentation and thecal pores
284 in the center of valves (Table 1). In contrast, in *P. bimaculatum* some pores are found in the
285 central area between the two circular patches located on both sides of the centre, which differs
286 from all the other *Prorocentrum* species known. Among benthic *Prorocentrum* species, *P.*
287 *bimaculatum* is a rather large species, exceeding 50 µm in length and thus only slight smaller

288 than *P. consutum* and *P. belizeanum* (Table 1). This new species is related to *P. consutum*, *P.*
289 *arenarium* and *P. lima* in having smooth valves bordered by a row of marginal pores (Table
290 1). From a very recent study, *P. arenarium* has been found to be a synonym of *P. lima* and
291 corresponds to a round morphotype of this species, which means that the outline shape of a
292 taxon is probably not a good taxonomic criterion (Nagahama et al. 2011). The smooth
293 intercalary band observed in *P. bimaculatum* is characteristic of other *Prorocentrum* species,
294 such as *P. belizeanum*, *P. foraminosum* Faust, *P. lima*, and *P. arenarium* (Faust et al. 2008).

295 In contrast with all these species, the presence of two kinds of pores in *P. bimaculatum*
296 has been noticed on one recently divided cell. Two sizes of thecal pores have been described
297 in several species such as *P. caribbaeum* Faust, *P. emarginatum*, *P. rhathymum*, *P. formosum*
298 Faust, *P. fukuyoi*, *P. elegans* Faust and *P. tsawwassenense*. Most of these species have an
299 asymmetrical morphology and belong to the clade 1 of *Prorocentrum* in phylogenetic studies.
300 Species of the clade 2 which are symmetric and mostly benthic have been reported with only
301 one kind of pores, either large as in *P. lima*, or small as in *P. consutum*. However, it is
302 remarkable that the smaller pores were only observed in a cell with a thin theca, while most of
303 other specimens were found to have large pores only. From this observation, small pores
304 could appear to be temporary during the cell development and they may clog or disappear
305 when the cellulosic theca thickens. The role of these pores is unknown yet.

306 The periflagellar area of *P. bimaculatum* is characterized by a wide triangular shape,
307 an insertion in a moderate excavation of the right valve and the presence of a short apical
308 ridge of the left valve, which is also found in other species such as *P. belizeanum*, *P.*
309 *consutum*, *P. hoffmannianum*, *P. sabulosum* Faust, and *P. reticulatum* Faust. However, an
310 apical ridge lacks in *P. arenarium*, *P. lima* and *P. maculosum*. Since the extension of some
311 platelets hide a part of the periflagellar area in SEM, it was necessary to study this small area
312 from the inside of the cell. The use of sectioning and TEM (Mohammad-Noor et al. 2007a)

313 could be used as a useful alternative method to complete these observations but it would be
314 difficult with only a few cells from an environmental sample fixed in Lugol and a culture
315 would be required. The number and arrangement of periflagellar platelets are very similar to
316 that of *P. consutum* with a platelet “a” split in two parts. However, the right valve of *P.*
317 *bimaculatum* is not as deeply excavated as in *P. consutum* and the apical ridge is shorter.
318 Similarly, the periflagellar platelets “a₁” and “d” in *P. consutum* form posteriorly extensions
319 which overlap the pore area and hide the structures located underneath (Chomérat et al. 2010).

320 The molecular genetic phylogenies inferred in this study are congruent with most
321 previous works on the genus *Prorocentrum*, and the split in two lineages has been found in
322 most of previous studies using ribosomal genes (Grzebyk et al. 1998, Saldarriaga et al. 2004,
323 Murray et al. 2007, Faust et al. 2008, Hoppenrath and Leander 2008, Chomérat et al. 2010).
324 The clade 1 groups mostly asymmetric species, or those with a variable morphology, living in
325 plankton or sand-dwelling while the clade 2 includes symmetric species, mostly sand-
326 dwelling (Faust et al. 2008, Hoppenrath and Leander 2008). This result seemed to indicate
327 that the genus *Prorocentrum* is polyphyletic, and in phylogenies inferred from SSU rDNA,
328 Murray et al. (2009) found that it was paraphyletic due to the presence of several intruders.
329 These findings may argue in favour of the reinstatement of *Exuviaella*, as proposed by
330 McLachlan et al. (1997). However, this suggestion has not been followed by taxonomists and,
331 from a morphological point of view, there are presumptions that *Prorocentrum* form a
332 monophyletic group in the evolution of dinoflagellates (Taylor 1980, Fensome et al. 1993).
333 The finding based on molecular analyses, that the group may be polyphyletic and that, by
334 implication, that the peculiar morphology of prorocentroid taxa may be an homoplasious
335 character in dinoflagellates, has appeared puzzling and inexplicable (Murray et al. 2009). The
336 monophyly of the genus has been demonstrated only recently, using multi-genes approaches

337 (Zhang et al. 2007) and including non nuclear genes such as mitochondrial genes like *cox 1*
338 (Murray et al. 2009).

339 Since the sequence of *Prorocentrum consutum* isolated from Kuwait grouped with
340 high support with the sequence from Brittany in our SSU rDNA phylogeny, this species is
341 identified unequivocally. The molecular characterization of this species confirms its
342 morphological identification and first report in another location than the type locality (Al-
343 Yamani and Saburova 2010a). Although *P. consutum* was originally described from a
344 temperate oceanic area (Chomérat et al. 2010), it appears from this study that it is also present
345 in Kuwait where the climate is typically arid and warm (BWh type in Köppen's classification,
346 Peel et al. 2007). Thus, the distribution of this species is not restricted to the temperate area
347 but it is probably widespread. In the phylogenetic analyses, *Prorocentrum bimaculatum*
348 appeared to be more closely related to *P. consutum* than to any other species of the clade 2,
349 which is consistent with the results obtained with morphology. However, its branch length
350 was rather long, indicating several differences between these two species which probably
351 evolved separately for a long period.

352 The capability to synthesize toxins appears to have arisen early in prorocentroid
353 evolution, and, in particular okadaic acid synthesis is present in several species of the clade 2
354 (Murray et al. 2009). At present, no study of any harmful effects by *P. bimaculatum* and *P.*
355 *consutum* (Chomérat et al. 2010) have been undertaken as cultures of these two species are
356 not available yet. However, the production of lipophilic toxins (also known as diarrhetic
357 shellfish poisons, DSP) such as okadaic acid and fast-acting toxins has been demonstrated for
358 all the closely related species in the clade 2, including *P. arenarium*, *P. belizeanum*, *P.*
359 *hoffmannianum*, *P. lima* and *P. maculosum* (Faust and Gullledge 2002). In addition, some
360 other species of the other subclade of clade 2, including *P. concavum*, *P. faustiae* and *P. levis*
361 are also known to produce DSP toxins (Faust and Gullledge 2002, Faust et al. 2008) but no

362 data are available for the unidentified strains (Murray et al. 2009). Consequently, from their
363 phylogenetic relationships *P. bimaculatum* and *P. consutum* could be considered as potential
364 toxin-producers and it would be of an utmost importance to assess their actual capability to
365 synthesize lipophilic toxins in a near future.

366

367 **Acknowledgements**

368 We extend special thanks to Audrey Duval for her help in the search of very rare cells of *P.*
369 *bimaculatum* and Nicolas Gayet for his skilled assistance with SEM. We are grateful to Dr.
370 Alain Couté for translating the description into Latin and to Sylviane Boulben and Karine
371 Chèze for their contribution to the molecular work. We would like to express thanks to Dr.
372 Igor Polikarpov for his valuable support and suggestions.

511

512 Fig. 22. ML phylogenetic trees inferred from SSU rDNA and LSU rDNA. (A) ML tree of
513 *Prorocentrum* species inferred from a SSU rDNA data matrix (34 taxa, 1712 characters). The
514 Likelihood value was found to be $\text{loglk} = -6760.32692$. The tree was rooted using *Scrippsiella*
515 sequences as outgroup. ML analysis was constrained by user-specified settings obtained from
516 jModelTest; model selected: GTR+I+ Γ_4 . Substitution rate matrix: $A \leftrightarrow C = 1.06439$, $A \leftrightarrow G =$
517 3.73789 , $A \leftrightarrow T = 1.05823$, $C \leftrightarrow G = 0.42569$, $C \leftrightarrow T = 8.57948$, against $G \leftrightarrow T$ set to 1.00000
518 (fixed). Assumed nucleotide frequencies: $f(A) = 0.26184$, $f(C) = 0.20010$, $f(G) = 0.26347$,
519 $f(T) = 0.27459$. Among-site rate variation: assumed proportion of invariable sites: $I = 0.504$.
520 Rates at variable site assumed to be gamma distributed with shape parameter: $\alpha = 0.709$.

521 Bootstrap values of ML (1000 replicates), posterior probabilities of BI (2,000,000
522 generations) and bootstrap values of MP (1000 replicates) are shown at nodes in order from
523 left to right, irresolutions noted with '-'. (B) ML tree inferred from a LSU rDNA data matrix
524 (26 taxa, 967 characters). The Likelihood value was found to be $\text{loglk} = -5884.81206$. The
525 tree was rooted using *Scrippsiella* sequences as outgroup. ML analysis was constrained by
526 user-specified settings obtained from jModelTest; model selected: TN93. Assumed nucleotide
527 frequencies: $f(A) = 0.22081$, $f(C) = 0.23378$, $f(G) = 0.27628$, $f(T) = 0.26913$. Among-site rate
528 variation: assumed proportion of invariable sites: $I = 0.149$. Rates at variable site assumed to
529 be gamma distributed with shape parameter: $\alpha = 0.793$. Bootstrap values of ML (1000
530 replicates), posterior probabilities of BI (2,000,000 generations) and bootstrap values of MP
531 (1000 replicates) are shown at nodes in order from left to right, irresolutions noted with '-'.

Table 1 : Comparison of morphological features of six benthic *Prorocentrum* species related to *P. bimaculatum* sp. nov., and placed in the same subclade of clade 2 in the phylogenetic analyses.
