In the North Atlantic there are more than ten extra-tropical storms every year with hurricane-force winds (Figure 1). Observing the dynamics and effects of these storms is a particular challenge
30 because in situ observations are scarce and opportunities to apply and validate remote sensing techniques for wind speeds above hurricane force and for phenomenal sea states are rare. We show here that a suite of data from different sources, a combination which may not be typical in forecasting environments, can give a remarkably coherent characterisation of an extreme storm event and associated wave fields. In February 2011 the North Atlantic storm Quirin produced the
35 ideal conditions to illustrate this synergetic approach.

Phenomenal seas, defined by the World Meteorological Organization (WMO) as having a significant wave height (H_s) larger than 14m^1 , were observed over the North Atlantic Ocean in February 2011. Three intense atmospheric low pressure systems followed the typical storm track
40 (seen in figure 1), from the north-eastern United States to the ocean area south-east of Greenland during the first half of the month. The storm Quirin rapidly followed the third of these, but took a more southerly route, depicted in the track overlaid on figure 1. The phenomenal sea states generated by this storm were observed by satellites, and produced extremely long swells along the western coast of Europe, which were observed by wave buoys and seismic stations. The ocean
45 conditions between the storm source and swell landfall can be determined using numerical wave models and a state-of-the-art model, WAVEWATCH-III [®] (WW3), was used to reproduce both the extreme sea states and subsequent swell fields generated by this storm.

Extratropical storm Quirin: the synoptic situation

50 This system was the last of four deep lows with hurricane-force winds that developed in close succession over the northern Atlantic. National Oceanographic and Atmospheric Administration

1 The term “phenomenal” is one level of the Douglas scale which is recommended for use by the WMO, see <http://www.wmo.int/pages/prog/amp/mmop/faq.html>

(NOAA) Ocean Prediction Center (OPC) synoptic analysis charts (Figure 2) show that on the 13th February, Quirin was south of Newfoundland, while the storm Paolini was still very active with hurricane-force winds blowing south of Greenland. By 00Z on the 14th, Quirin had moved to the
55 northeast at a speed of 23.6m/s and had rapidly intensified by 34hPa in 24 hours, well above the threshold for 'bombogenesis' (Sanders and Gyakum 1980).

Figure 3 presents the National Centers for Environmental Prediction (NCEP) wind analyses for the 13th and 14th at 12 hour intervals for comparison with observations from the Advanced
60 SCATterometer (ASCAT) on board MetOp and from the Indian Oceansat-2 scatterometer. Two altimeter tracks (black lines) crossed the storm when it was close to its maximum intensity. The NCEP wind analysis gives a maximum wind speed of 27.9 m/s at 00Z on the 13th, slightly above the 25.1 m/s from ASCAT and indicates that Quirin had reached hurricane-force intensity by 09Z (not shown). The ASCAT pass at 12:44 confirms this and maps out a storm-force wind envelope similar
65 to that of the NCEP field at 12Z, although it is rotated around the storm center, possibly due to the time difference. The maximum NCEP wind speed of 35.1 m/s is very close to the 35.3 m/s estimated from ASCAT at this time, probably as ASCAT winds are assimilated in this analysis. At 00Z on the 14th, the size and shape of the hurricane-force winds are still visually in close agreement, with the maximum NCEP wind speed now lower than the 39.8 m/s ASCAT value by only 1.6m/s. A
70 couple of hours later, a complementary Oceansat-2 scatterometer pass (bottom right panel of figure 3) shows a wide area with hurricane-force winds reaching up to 44.7 m/s.

These maximum wind estimates are difficult to validate. As frequently reported in the Mariners Weather Log (MWL) publications, the ASCAT values are likely to be underestimated at high wind
75 speeds and the reported maximum values for Quirin possibly suffer large errors (see supplementary material, data section, for less cursory discussion and Quilfen et al. (2010) for a review of the

satellite measurements' techniques and limitations). More direct intercomparison between different sources may help to further identify the useful high wind scales. Satellite altimeters provide high resolution (~ 5 km) estimates of H_s but also of high wind speeds that have been calibrated by
80 comparison with the QuikScat winds (Quilfen et al. 2011). QuikScat data have long been a standard for operational forecasters and QuikScat high wind estimates are more accurate than the ASCAT ones (see supplementary information). Altimeters are thus likely to bring useful information although measurements are performed along a narrow ground track. The bottom panels in Figure 4 display the wind speed from different sources (NCEP, satellite scatterometers, altimeters,
85 radiometers) interpolated to the Envisat and Jason-2 altimeter tracks shown in figure 3. Beyond hurricane-force, the estimated maximum winds can differ significantly, partly because of the different resolution of the datasets, but the general agreement of all sensors up to hurricane-force winds is remarkable. It shows that information is available to estimate the scales over which Quirin winds reached gale, storm, and hurricane-force, given a good knowledge of the sensors limitations.
90 Although the ASCAT and altimeter coverage is insufficient to completely map the storm, the bottom panels in Figure 4 indicate that the NCEP winds underestimate the storm and hurricane-force radii as well as the maximum values for the available passes.

Figure 4, middle panels, shows H_s values recorded by satellite altimeters on February 13th and 14th,
95 together with the values predicted by the WW3 numerical model. Wave heights in excess of 10m were generated by Paolini over a large part of the Atlantic Ocean, north of 50°N on the 13th. Later on the same day, the Envisat altimeter measured a maximum H_s value of 18.1m under Quirin's hurricane-force winds. The day after, Quirin had generated phenomenal seas over a 533km long track with a maximum of 20.1m reported by the Jason-2 altimeter. Such exceptional values were
100 emphasized in the 2011 December issue of MWL: “*Altimetry data from 1100 UTC on the 14th (Figure 13) reveal seas as high as 66 ft (20.1 m), the highest the author has seen in this type of*

imagery” (Bancroft, 2011).

As for the wind observations, these extreme H_s values are outside the validated range of altimeter
105 H_s measurements (see supplementary material for discussion). In spite of the lack of an absolute
accuracy estimate of the extreme values, an analysis of the entire Jason-1 and Jason-2 H_s data set
(January 2002 to December 2011) showed that Quirin produced the largest individual 1 Hz
measurement (20.1m). Another indicator of sea state is the average H_s of all measurements greater
than 14m along a satellite pass in the vicinity of a storm, and Quirin also produced the highest
110 along-track average (16.2m over 533 km) over this 9-year period.

The wave field generated by Quirin was hindcast with WW3 forced by ECMWF and NCEP wind
analysis (see supplementary information for details). The middle panels in Figure 4 show the H_s
along the satellite track when using European Centre for Medium-Range Weather Forecasts
115 (ECMWF, red) and NCEP (green) analyses winds. It can be seen that the model performs well both
at generating the high H_s observed by satellites and at reproducing these phenomenal seas over such
large scales. The NCEP values were increased by 10% to better match the satellite-based wind
measurements, which resulted in better prediction of the extreme H_s values by the wave model
(blue).

120

Storm swell observations and modelling

Complementary satellite information on the swell emerging from the storm was provided by wave
mode images from Envisat's Advanced Synthetic Aperture Radar (SAR). The SAR clearly revealed
a peak wavelength of 700m (corresponding to a period of 22 s) emerging from the region of the
125 storm at 23:23 on 14th February (Figure 5) near 58.5°N, 29.5°W.

Additional spectral information is available from buoys, located from the Azores along western Europe as far north as Scotland. Figure 5 (top panel) shows that the H_s observed by the buoys is considerably reduced from the high open ocean values, because of swell dispersion and dissipation (Ardhuin et al. 2009), while all of the maximum peak periods ($T_{p_{max}}$) observed were above 20 s. Time series of the peak periods (not shown) show very clearly the arrival of $T_{p_{max}}$ at each wave buoy, first at the Azores with waves of period 21s observed approximately 24 hours after the winds generated by Quirin reached hurricane-force. Over the next 24 hours, $T_{p_{max}}$ was observed arriving at many buoys along the western coast of Europe and at the Canary Islands, reaching over 23s off the west coast of France and up to 25s to the west of Scotland and north of Spain.

Land-based seismometers can provide a very useful complement to buoy observations as the background seismic noise, mostly generated by ocean waves, can propagate from a localised storm source area over distances of thousands of kilometers. Non-linear interaction between waves having similar frequencies and moving in almost opposite directions generates seismic waves at twice the wave frequency, producing a peak in the seismic spectrum, typically at 0.08-0.3 Hz (Bernard 1941, see supplementary information for more detail).

The bottom panel of figure 5 shows the 3 hour median of the vertical ground displacement variance of several seismic stations around the North Atlantic, from February 14th to 16th. These were filtered to keep only the energy corresponding to swell with periods longer than 20 s. On February 14th, a peak was observed at station CMLA in the Azores, about 12 hours before the arrival of $T_{p_{max}}$ observed by the wave buoy at the same location. The seismic stations in Scotland, Iceland and Greenland observed an increase in seismic noise starting after midday on the 14th, with peaks occurring on the 15th for the stations based on continental Europe. The maximum level was reached around noon on the 15th, coinciding with the arrival of peak periods at the wave buoys along the

coasts of western Europe (top panel, figure 5).

In the seismic record of the CMLA station for February 14th and the European stations in the evening of February 15th, the strong noise level in the double-frequency band (see supplementary material) is accompanied by a lower energy peak below 0.05 Hz. This indicates that the source is at least partly associated with waves reaching the shore (Hasselmann 1963). On the contrary, the local maxima recorded in Iceland and Scotland, at 00Z to 03Z on February 15th are not associated with a significant low frequency noise and are probably due to the strong rotation of winds and waves inside Quirin. Indeed, our wave model predicts that a very intense noise source was centered at 54°N 28°W at that time.

In the top panel of figure 5 the peak periods of the swell field output from the WW3 model, forced by NCEP winds increased by 10% in magnitude, are shown, as discussed in the previous section. With this correction, the maximum wave heights at the peak of the storm are within 5% of the observations, while the $T_{p_{max}}$ reach 20 to 24 s (figure 5) as the longer waves reached European shores. The peak periods, the timing of the swell arrival, and the associated wave heights are in very good agreement with the buoy and seismic station observations around the basin, showing that the current generation of wave models are capable of both reproducing the observed phenomenal sea states and accurately predicting the subsequent propagation of the swell field.

Quirin in historical perspective

Numerical wave models can be used to provide a full space-time coverage of the global sea state and although the wave heights they produce are generally biased low for phenomenal seas, the random error is relatively small, typically under 10% (Ardhuin et al. 2010). Here we use a consistent model hindcast forced by Climate Forecast System Reanalysis winds (Saha et al. 2010),

from 1994 to 2010, along with NCEP analysis winds for 2011. Over a 12 year period (1999-2011), the maximum H_s value obtained for Quirin put the storm in 13th position globally, and 3rd over the North Atlantic, being about 2m less than the record H_s produced by Tropical Cyclone Yasi which
180 made landfall in Northeast Australia on February 2, 2011.

Because these wave model estimates are as uncertain as the wind fields used as input, the long time-series of seismic data available at several stations around the Atlantic Basin offer an interesting independent observation. As analysis of the low frequency seismic noise provides information on
185 the longest periods generated by a given storm, it may be tentatively used to quantify the relative importance of major events such as Quirin. For the years 1996 to 2011, only seven storms produced an rms noise larger than 0.25 μm in the 0.08 to 0.1 Hz band at station CMLA (Azores), whereas Quirin registered 1 μm . This work confirms that the low frequency noise level is a good indicator of storm intensity, as proposed by Ebeling and Stein (2011) for the investigation of hurricanes. The
190 interpretation of seismic noise records is complicated by the fact that the noise level observed by a seismometer depends on the storm trajectory as well as the intensity. Further work will focus on the analysis of historical wave hindcast and seismic records to investigate the potential of seismic measurements for storm intensity analysis.

195 **Discussion**

Following Kahma and Calkoen (1992), and assuming that the usual fetch laws apply at high wind speeds, we expect that peak periods of 23s can be formed by wind speeds exceeding 40 m/s over at least two days or even stronger winds over a shorter duration. This crude analysis suggests that either the wind was in reality higher than the maximum winds given by numerical weather analyses
200 and scatterometers over a longer time period, or some mechanism greatly enhanced the transfer of energy from wind to waves over a shorter period of time.

Apart from the wind strength, several conditions may have allowed exceptional growth of the wind sea at this time. The hurricane-force winds associated with Quirin blew over a sea already
205 roughened by Paolini, which can be seen in the top panels of figure 4, which may have enabled a faster growth for the wind sea. Numerical wave modelling tests suggest that, in fact, the sea state before Quirin had little effect on the magnitude of the wave heights or periods.

A more likely explanation for the extreme sea state is a resonance phenomenon, which occurs when
210 the storm displacement speed roughly equals the group speed of the dominant waves, so the waves are continuously fed by the wind input. The Quirin storm speed at approximately 20 m/s between the 13th at 12Z and the 14th at 00Z (table 1) corresponds to the group velocity of waves with a period of about 26s in deep water, a value close to the largest wave periods observed near the coasts. The same phenomenon explained all of the very high sea states reported in the North
215 Atlantic (Cardone et al. 2011; Holliday et al. 2006)

The North Atlantic extra-tropical storm Quirin produced, on 14th February 2011, wave heights that are expected to occur only about once a year over the globe, according to our hindcast results. Waves from the center of the storm radiated as swell with very long periods, from 20 to 25 s, and
220 were recorded around the northern and eastern Atlantic basin. Although the maximum values for wind and wave estimates are difficult to validate, the evidence presented in this study gives credence to the observed scales over which hurricane-force winds and sea state developed. Once the forcing wind field was adjusted to better match the satellite observations, a numerical wave model performed very well in reproducing the local sea state and swell field around the basin, given the
225 extreme input conditions.

We are encouraged by these results to report that our ability to both model and observe extreme wave events has improved greatly in recent years, while a novel look at century-old seismic records will help refine the climatology of such rare events.

Figure 1. Annual average frequency of the low pressure centers with hurricane-force winds based
235 on the NOAA OPC 6-hourly surface pressure analyses and QuikSCAT winds. Average was
calculated based on data from September through May 2002-2009. The track of Quirin at 6-hourly
intervals from 00Z on 13th February till 18Z on 14th February is overplotted. The size of the circle
symbol at each time step reflects the surface area of winds ≥ 24.5 m/s and the colour represents the
maximum wind speed, see table 1 for details.

240

Figure 2. NOAA OPC synoptic analysis charts for 00Z on the 13th (left) and on the 14th February
2011 (right). On the 13th, Quirin was near 42N 60W at 984 hPa and expected to track northeast
(arrow) and intensify to hurricane force (DVLPG HURCN FORCE label) while Paolini (HURCN
245 FORCE label) was southeast of Greenland. By 00Z on the 14th Quirin had intensified to 950 hPa
with hurricane-force winds and moved to 50.5N 38W.

Figure 3. Top: NCEP wind analyses every 12 hours at synoptic times starting February 13th 2011 at
250 00Z (left), ending February 14th 2011 at 12Z (right). Two storms are active on the 13th, Paolini
southeast of Greenland and Quirin traveling south of Newfoundland.

Bottom: Scatterometer winds available for that time period: ASCAT winds (three left panels) from
passes within an hour of the above corresponding panel; and Oceansat-2 winds (right panel) at
255 01:52 UTC on the 14th for comparison with the 3rd ASCAT overpass. Thick black lines show the
paths of the two altimeters which crossed the area of storm-force winds, Envisat at ~00Z and Jason-
2 at ~12Z on the 14th. NCEP and scatterometer times and the maximum wind speed (V_{max}) in the

Quirin storm are indicated in each panel title. Contours of storm force winds (cyan, $V \geq 24.5$ m/s) and of hurricane-force winds (magenta, $V \geq 32.7$ m/s) are included to aid visualisation of the storm intensity.

Figure 4. Top: altimeter H_s measured by 4 altimeters (Jason-1, Jason-2, ERS-2 and Envisat) on February 13th (left panel) and February 14th 2011 (right panel). The black square in the left (right) panel indicates the location of the most extreme sea states measured during these two days by the Envisat (Jason-2) altimeter, respectively.

Middle: Focus on the altimeter (black) H_s values estimated along the Envisat (left) and Jason-2 (right) tracks shown in figure 3 and indicated by the squares above, and computed from the WW3 model forced by ECMWF (red), NCEP (green) and NCEP+10% (blue) winds. A running average has been applied to the altimeter data (~5km resolution) to better match the resolution of the WW3 model (0.5°).

Bottom: Wind speed from different sources interpolated on the same Envisat (left) and Jason-2 (right) altimeter tracks. For both panels, black (green) lines give the altimeter (NCEP) wind speed. For the left (right) panel, the dashed red line gives the ASCAT scatterometer (Jason-2 radiometer) wind speed. On the left panel, the blue line gives the Oceansat-2 wind speed. All estimates have been computed at the spatial resolution of the NCEP fields. The dashed blue lines show the storm force ($V \geq 24.5$ m/s) and hurricane-force ($V \geq 32.7$ m/s) wind thresholds. A running average was again applied to the altimeter data to better match the resolution of the other data sources (~25km).

Figure 5. Top: Peak periods of the swell field: as calculated by WW3; from SAR observations; from wave buoy data; and from seismic buoy data. The background shows the output from the model at 12Z on the 15th, as the longest swells were encroaching on the west coast of Scotland. The square symbols represent the wave buoy data, the size of the symbol signifying the H_s at the time of the maximum peak period observed and the color signifying the value of the peak period at this time. Beside each symbol is printed the time of arrival of the maximum peak period at each buoy. The circle gives the location of the SAR observations and diamond symbols represent the seismic stations, also colored according to the peak periods observed.

Bottom: Time series of the 3 hour median of the vertical ground displacement variance averaged over 20 minutes, from several stations around the North Atlantic, from February 14th to 17th. A timeseries of H_s from a buoy (OLERON) located off the west coast of France is also shown.

Figure 2. NOAA OPC synoptic analysis charts for 00Z on the 13th (left) and on the 14th February 2011 (right). On the 13th, Quirin was near 42N 60W at 984 hPa and expected to track northeast (arrow) and intensify to hurricane force (DVLPG HURCN FORCE label) while Paolini (HURCN FORCE label) was southeast of Greenland. By 00Z on the 14th Quirin had intensified to 950 hPa with hurricane-force winds and moved to 50.5N 38W.

325

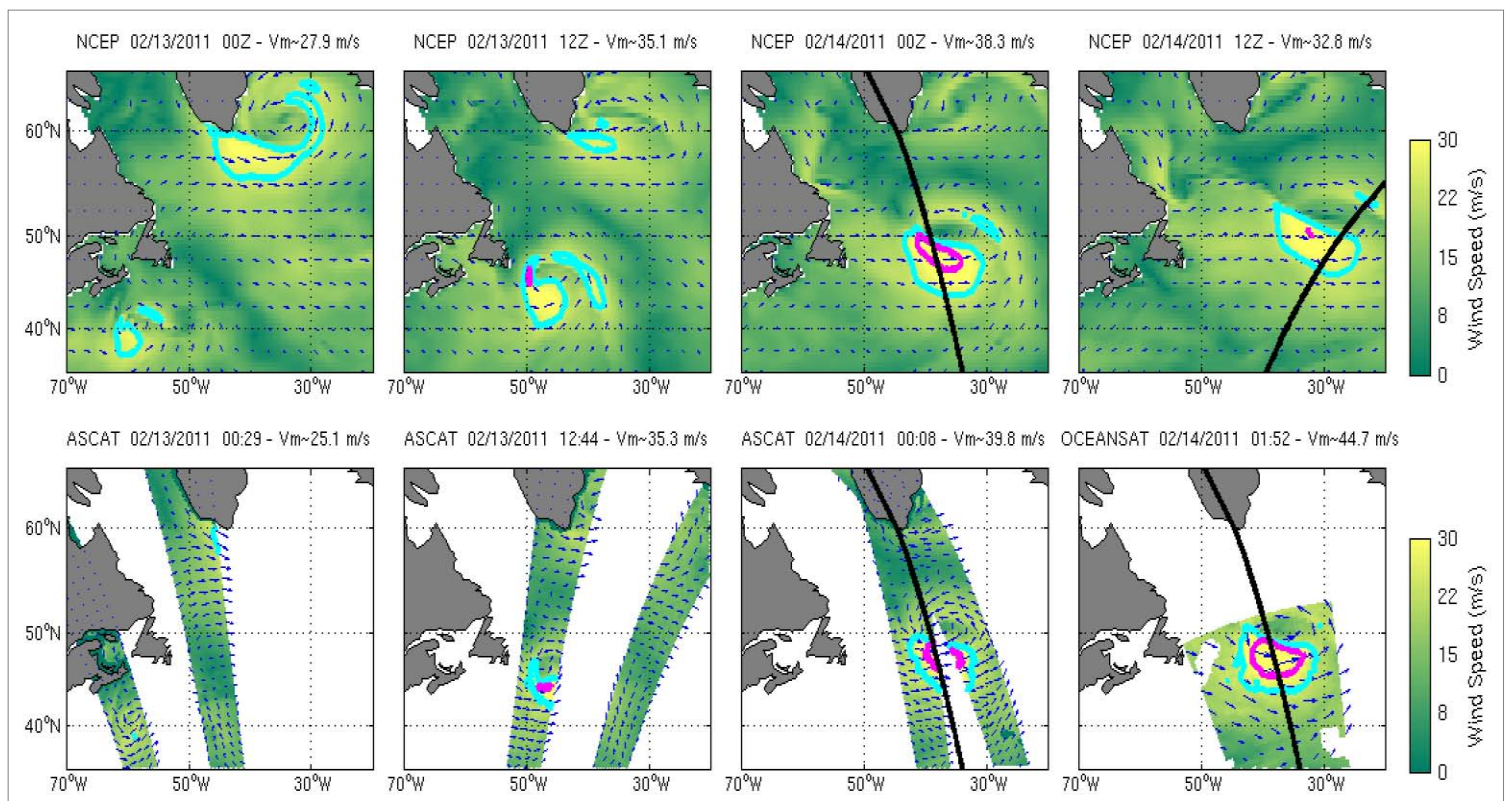

Figure 3. Top: NCEP wind analyses every 12 hours at synoptic times starting February 13th 2011 at 00Z (left), ending February 14th 2011 at 12Z (right). Two storms are active on the 13th, Paolini 330 southeast of Greenland and Quirin traveling south of Newfoundland.

Bottom: Scatterometer winds available for that time period: ASCAT winds (three left panels) from passes within an hour of the above corresponding panel; and Oceansat-2 winds (right panel) at 01:52 UTC on the 14th for comparison with the 3rd ASCAT overpass. Thick black lines show the 335 paths of the two altimeters which crossed the area of storm-force winds, Envisat at ~00Z and Jason-2 at ~12Z on the 14th. NCEP and scatterometer times and the maximum wind speed (V_{max}) in the Quirin storm are indicated in each panel title. Contours of storm force winds (cyan, $V \geq 24.5$ m/s) and of hurricane-force winds (magenta, $V \geq 32.7$ m/s) are included to aid visualisation of the storm intensity.

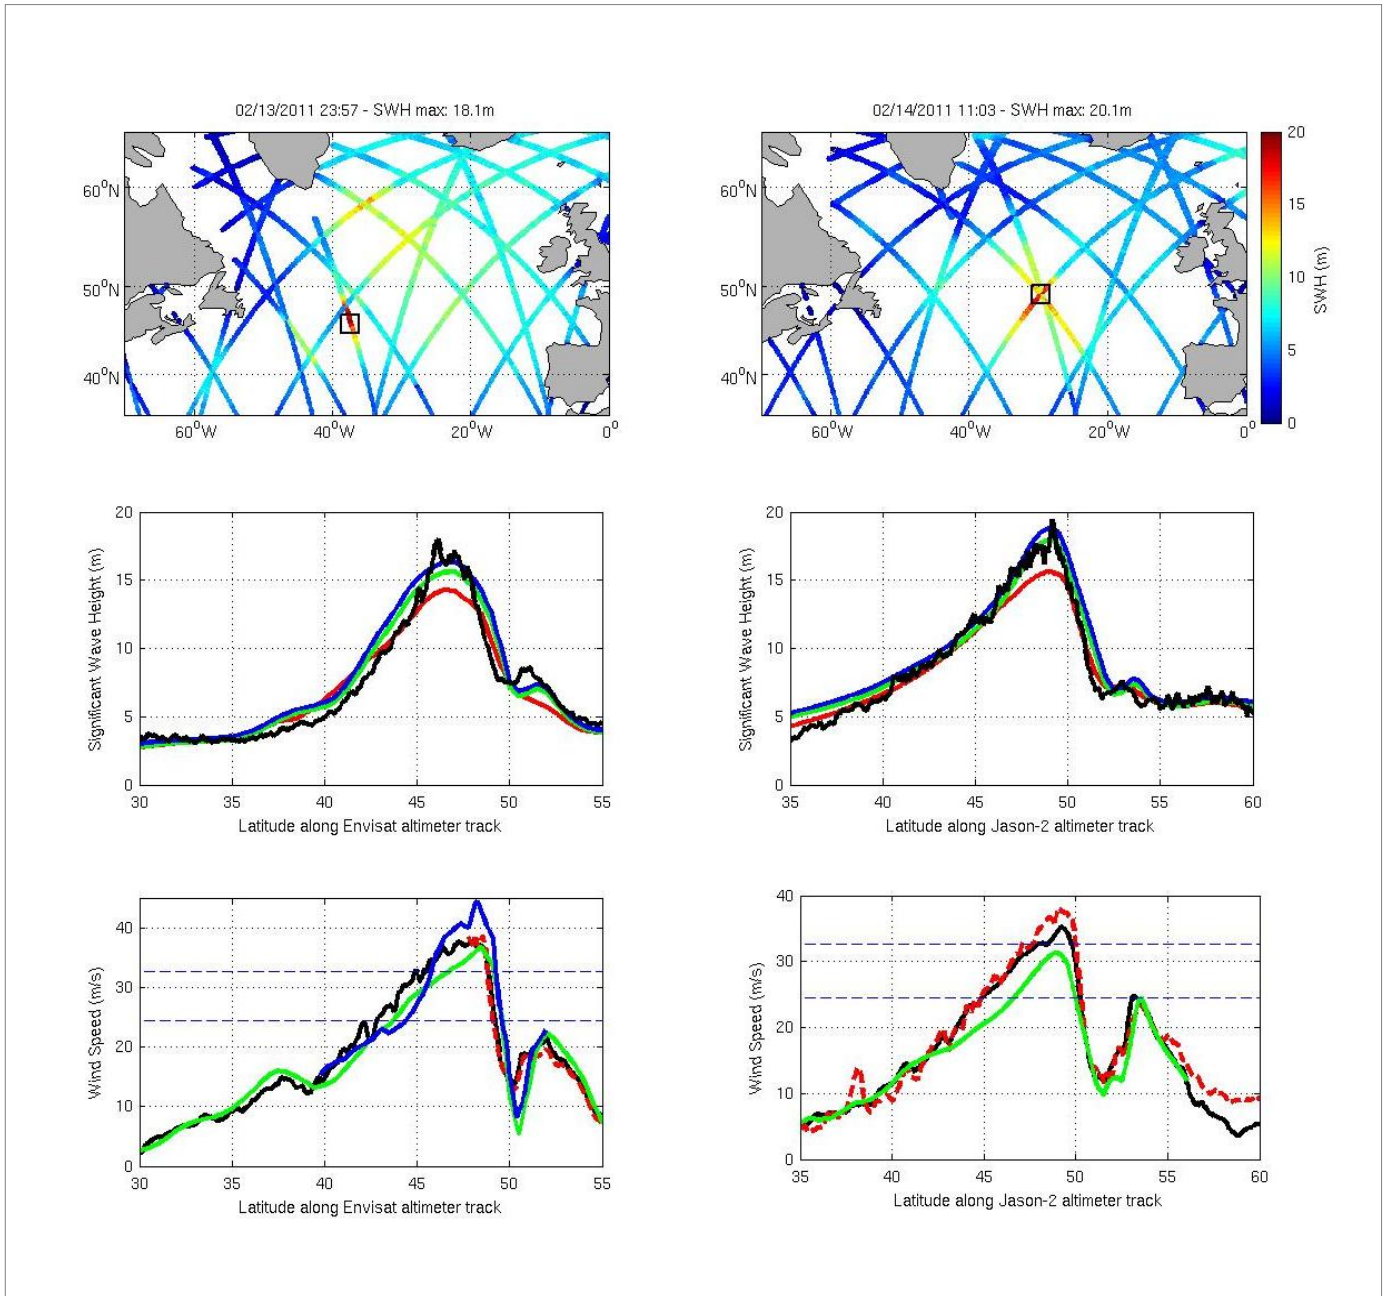

Figure 4. Top: altimeter H_s measured by 4 altimeters (Jason-1, Jason-2, ERS-2 and Envisat) on February 13th (left panel) and February 14th 2011 (right panel). The black square in the left (right) panel indicates the location of the most extreme sea states measured during these two days by the Envisat (Jason-2) altimeter, respectively.

Middle: Focus on the altimeter (black) H_s values estimated along the Envisat (left) and Jason-2 (right) tracks shown in figure 3 and indicated by the squares above, and computed from the WW3 model forced by ECMWF (red), NCEP (green) and NCEP+10% (blue) winds. A running average
350 has been applied to the altimeter data (~5km resolution) to better match the resolution of the WW3 model (0.5°).

Bottom: Wind speed from different sources interpolated on the same Envisat (left) and Jason-2 (right) altimeter tracks. For both panels, black (green) lines give the altimeter (NCEP) wind speed.
355 For the left (right) panel, the dashed red line gives the ASCAT scatterometer (Jason-2 radiometer) wind speed. On the left panel, the blue line gives the Oceansat-2 wind speed. All estimates have been computed at the spatial resolution of the NCEP fields. The dashed blue lines show the storm force ($V \geq 24.5$ m/s) and hurricane-force ($V \geq 32.7$ m/s) wind thresholds. A running average was again applied to the altimeter data to better match the resolution of the other data sources (~25km).

360

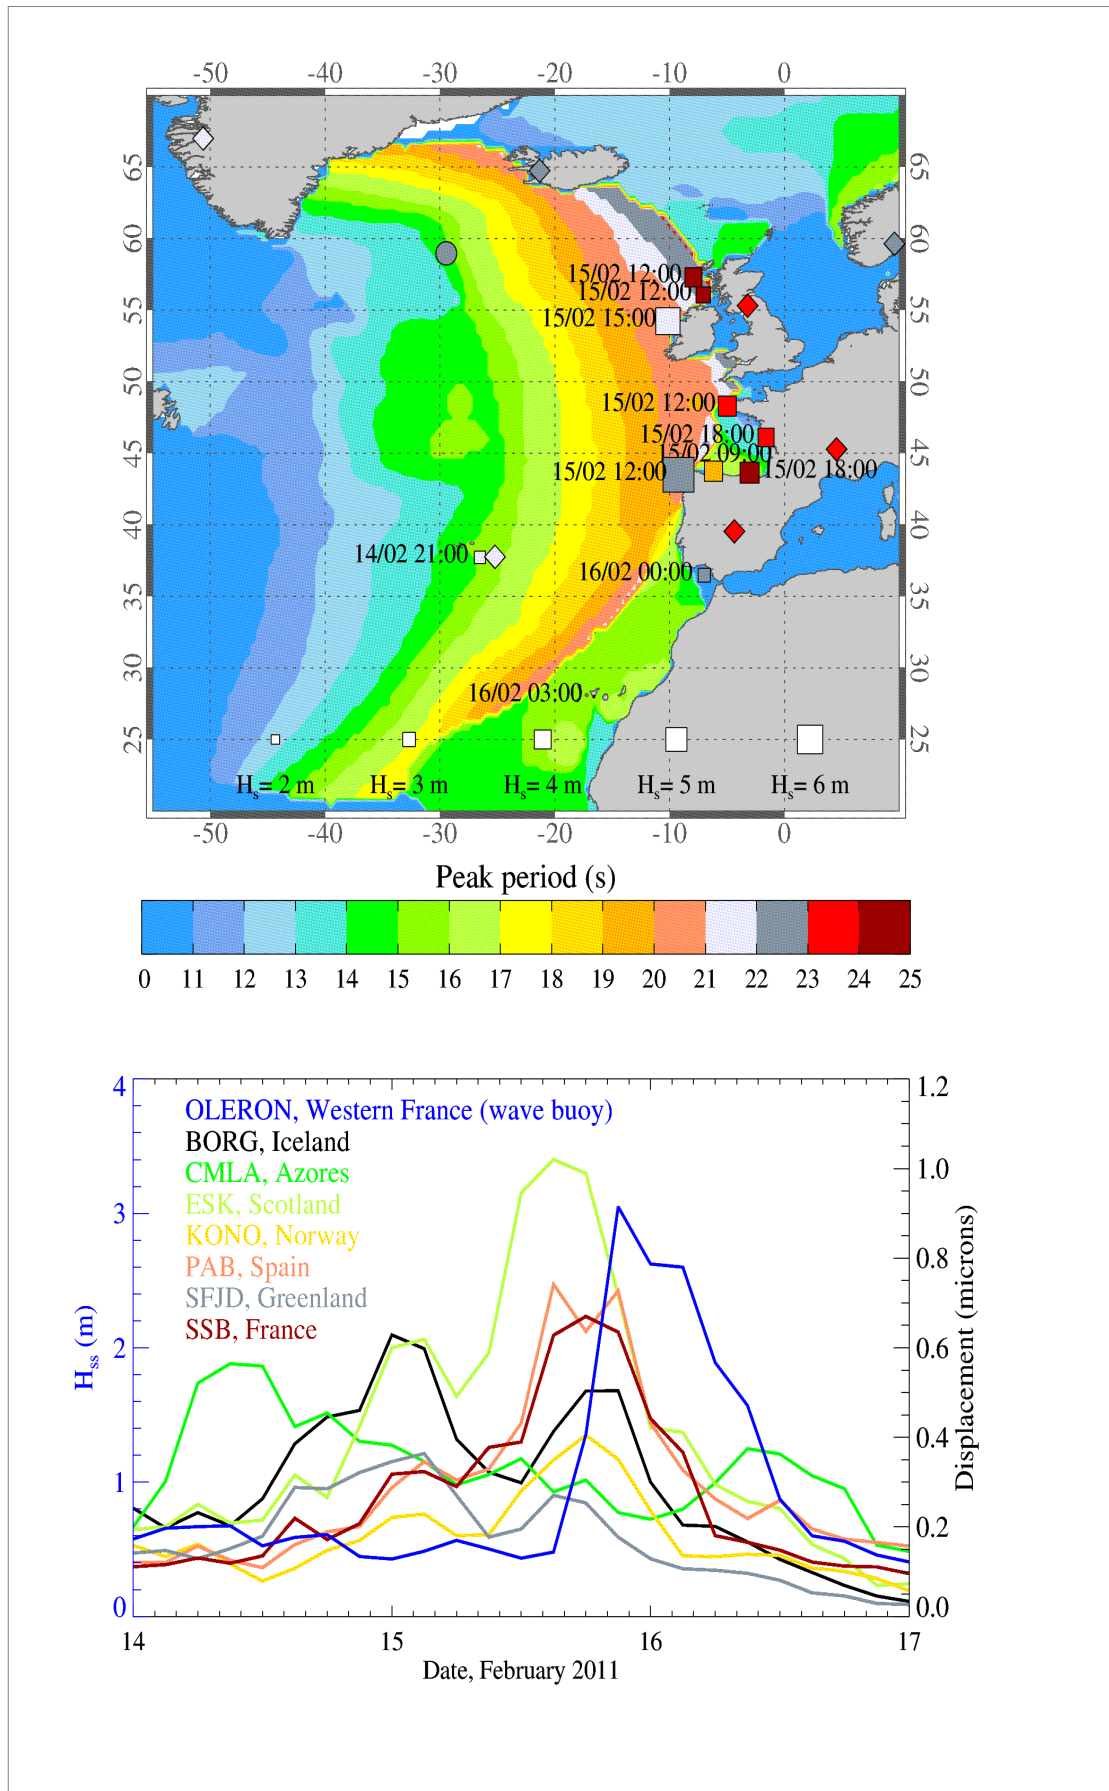

Figure 5. Top: Peak periods of the swell field: as calculated by WW3; from SAR observations; from

365 wave buoy data; and from seismic buoy data. The background shows the output from the model at
12Z on the 15th, as the longest swells were encroaching on the west coast of Scotland. The square
symbols represent the wave buoy data, the size of the symbol signifying the H_s at the time of the
maximum peak period observed and the color signifying the value of the peak period at this time.
Beside each symbol is printed the time of arrival of the maximum peak period at each buoy. The
370 circle gives the location of the SAR observations and diamond symbols represent the seismic
stations, also colored according to the peak periods observed.

Bottom: Time series of the 3 hour median of the vertical ground displacement variance averaged
over 20 minutes, from several stations around the North Atlantic, from February 14th to 17th. A
timeseries of H_s from a buoy (OLERON) located off the west coast of France is also shown.

Supplementary Information

Altimetric observations at high wave heights

390 While estimates of H_s at high sea-states are considered to be relatively robust, altimeters are neither designed nor calibrated for such large values. Here, however, the lack of evidence of saturation errors in the sensor waveform data, the consistency of the along-track patterns in the full 20 Hz data and the low 1Hz standard deviation (1.46m) all give a measure of confidence in these measurements. This is supported by the consistency between the very high waves and the long
395 swells which is presented in this study. In general H_s measurements from altimeters are calibrated using buoy comparisons and inter-altimeter comparisons (Queffeuilou 2004). Recent analysis of Jason-2 observations (Queffeuilou and Croizé-Fillon 2010) indicates that a slight linear correction to H_s should be applied, which would give a maximum value of 20.4m rather than 20.1m on the 14th February. As this correction was estimated using very few buoy observations between 8m and 12 m
400 and none above 12m, the very high altimeter H_s values are not directly validated, and estimation of the error in the measurement is difficult.

Discussion of high wind speed retrieval from satellites

Calibration at high wind speeds is one of the goals of the "International Ocean Vector Winds
405 Science Team" and performing cross-calibration for different satellite sensors with reference in situ data is an active topic of research. The comparison of the winds in Quirin up to hurricane-force between the altimeter and radiometer onboard Jason-1 and Envisat and the ASCAT scatterometer shows that the gale-, storm- and hurricane-force wind scales can be consistently estimated (see also Quilfen et al., 2011). The ultimate goal of having accurate measurements of high wind speeds from
410 sensors operating at different resolutions and on different principles, however, is a topic requiring considerable further research. Satellite-based high wind speed retrievals are difficult to obtain and

the errors associated with the measurements are difficult to characterize for three main reasons discussed in Quilfen et al. (2010) and outlined below.

415 **1) Saturation at high wind speed.**

Using aircraft data, Fernandez et al. (2006) found that active measurements of the radar cross-section (RCS) can saturate with increasing wind speed and the RCS may even decrease beyond a given wind speed value. This behavior depends on the instrument characteristics such as the wavelength, polarization and incidence angle. The high incidence angles and horizontal polarization
420 of the QuikSCAT scatterometer makes it more sensitive at high winds than the ASCAT instrument. Passive radiometric measurements of brightness temperatures is not affected as much by the issue of saturation (Quilfen et al., 2007; Reul et al., 2010), but the coarser resolution of satellite-based radiometers is not ideal for high wind speed retrievals.

425 **2) Calibration / validation issues.**

The usual specifications for a satellite instrument designed to observe winds is an accuracy of 2 m/s and 20 degrees for winds up to 24 m/s. Very few reliable reference data are available beyond that threshold, equivalent to storm-force winds, for calibration of the instruments' geophysical model functions (GMF), so errors are likely to be greater. For example, the ASCAT GMF has been shown
430 to overestimate the RCS sensitivity at high wind speeds when compared with QuikSCAT high winds, resulting in underestimation of high winds (Soisuvarn et al., 2009). This is common knowledge among operational forecasters and is often mentioned in the Mariner Weather Log publications. On the other hand, although the QuikSCAT winds are sometimes considered a 'reference' measurement, as the GMF has been tuned to passive radiometer measurements whose
435 sensitivity to high winds does not saturate, comparisons with well-calibrated platform measurements have shown that they can, in fact, overestimate winds (with a mean positive bias of 3

m/s above 25 m/s, as shown by Cardone et al., 2009). Validation of the OceanSat-2 scatterometer to refine its GMF in high wind speeds is currently underway.

440 **3) Representativity of the Geophysical Model Function (GMF)**

Satellite sensors which are sensitive to surface turbulent wind stress are calibrated to equivalent neutral winds due to the paucity of stress observations (Bourassa and Weissman, 2008) and the effect of atmospheric stability on the GMF is effectively ignored. Other geophysical effects, such as the surface current and the degree of development of the sea state can also impact the surface stress
445 and modify the measured RCS for a given neutral wind speed, but are not accounted for in the GMF. In stormy conditions the sea maturity is very variable and the retrieved satellite winds can have errors of several m/s as a result (Quilfen et al., 2001; Plagge et al., in review 2012).

Data

450 **Wave buoy processing**

1-D spectra from the buoys were averaged over periods of either 2 or 3 hours, depending on the noise level of the spectra. The spectra were partitioned using the 1-D algorithm proposed by Portilla et al. (2009), which removes partitions above a certain frequency threshold, those with low total energy, those spanning few spectral bins and those which fall between two other peaks which both
455 have higher energy. The swell was identified using the ratio between the peak energy of a partition and that of a Pierson-Moskovitz spectrum at the same frequency (Pierson and Moskowitz 1964). When this ratio is less than one, the partition is considered to be swell rather than wind sea. The peak at the lowest frequency was taken as that emanating from the Quirin storm, as directional information was not available for most buoys.

460

WW3 model runs

The numerical model hindcasts were run on a quasi-global grid, with a resolution of 0.5° in latitude (79.5°S to 79.5°N) and longitude (-180°E to 180°W). The model numerical schemes are described by Tolman (2008), including third order schemes with garden-sprinkler correction (Tolman 2002),
465 subgrid island and iceberg blocking (Ardhuin et al. 2011a; Tolman 2003). The parameterizations combine the Discrete Interaction Approximation (Hasselmann et al. 1985), a wind-wave generation term adapted from Janssen (1991, see Ardhuin et al. (2010) for the adjustment details) and dissipation parameterizations (Ardhuin et al. 2010). The model uses 24 directions and 32 frequencies (0.037-0.72Hz) In the cases shown here, the hindcast was run from December 1st 2010
470 until February 28th 2011, with output every 3 hours. Forcing was provided by NCEP analysis winds corrected globally by a 10% factor.

Seismic station analysis

Seismic noise at different frequencies has been correlated with different types of generation
475 mechanisms due to waves. Waves interacting with the shore, for example, produce a modest primary peak, at the same frequency as the waves, typically in the 0.05-0.1 Hz frequency band (Hasselmann 1963; Haubrich et al. 1963). Non-linear interaction between waves having similar frequencies and moving in almost opposite directions produces pressure perturbations at the ocean surface that excite seismic Rayleigh waves in the ocean and crust waveguide with frequencies
480 double that of the interacting waves (Longuet-Higgins 1950). This phenomenon yields a stronger secondary peak in the 0.1-0.3 Hz frequency band. This type of secondary micro-seismic generation can be found inside storms. It can also result from wave reflection at the shore or from the encounter of two swells or a swell and a wind sea that may come from the same or from different sources (Ardhuin et al. 2011b). Here, the 3-hourly and the daily medians of the vertical ground
485 variance were calculated from filtered spectra for the February 2011 study and 15-year climatology, respectively.
