Abstract. The recent discovery of voluminous submarine landslides along the Owen Ridge may represent a source of tsunami hazard for the nearby Oman coast. We assess the severity of this potential hazard by performing numerical simulations of tsunami generation and propagation from the biggest landslide (40 km³ in volume) observed along the Owen Ridge. A finite-difference model, assimilating the landslide to a visco-plastic flow, simulates tsunami generation. Computation results show that Salalah city (190 000 inhabitants) is impacted by 2.5 m-high tsunami waves one hour after sediment failure. Higher wave elevation values (4 m) are reached in the low populated Sawqara Bay over 80 min after slide initiation. Although large submarine failures along remote oceanic ridges are infrequent, this study reveals an underestimated source of tsunami hazard in the Arabian Sea.

1 Introduction

Arabian Sea coasts have been affected by numerous and disastrous tsunamis in the past (Jourdan, 2008; Heidarzadeh et al., 2008; Donato et al., 2008, 2009; Jaiswal et al., 2009; Pilarczyk et al., 2011; Pilarczyk and Reinhardt, 2012) and storm waves from cyclones (Fritz et al., 2010). The main tsunami source in the Arabian Sea is the seismic activity of the Makran subduction zone, which caused the 1945 event ($M_w = 8.1$) and the subsequent 4000 human fatalities. Other far field sources, such as the seismic activity of the In-

doneasian subduction zone, may generate modest tsunamis on Arabian Sea coastlines (Okal et al., 2006). Although previous studies have identified submarine landslides as the source of some of the deadliest tsunamis over the last decades (for instance the 1998 Papua New Guinea event (Heinrich et al., 2000; Tappin et al., 2001, 2008)), the severity of such hazard remains unknown in the Arabian Sea.

Tsunamis are dispersive gravity water waves with a phase velocity $c = \sqrt{gh}$ at long period, where h is the bathymetry and g the gravitational acceleration. Submarine landslide-generated tsunamis display distinct differences compared to earthquake-generated tsunamis (Trifunac and Todorovska, 2002): because of their smaller source dimensions, landslide-generated tsunamis are more affected by frequency dispersion, resulting in shorter wavelength and faster wave amplitude attenuation. However, vertical displacements at the source can be larger in comparison to earthquake source, and lead to potentially higher amplitude waves, which requires the consideration of non-linearity of the propagating waves.

The recent discovery of voluminous submarine landslides along the Owen Ridge may represent an under-estimated source of tsunami hazard in the Arabian Sea (Fournier et al., 2011). The Owen Ridge is a prominent submarine relief located 300 to 400 km away from the coast of Oman and is closely linked to the Owen Fracture Zone, a 800 km-long active strike-slip fault system (Rodriguez et al., 2011; Bourget et al., 2013) (Fig. 1). Several types of mass failures have been mapped in details along the ridge using multi-beam bathymetry and sediment echo-sounder (Rodriguez et

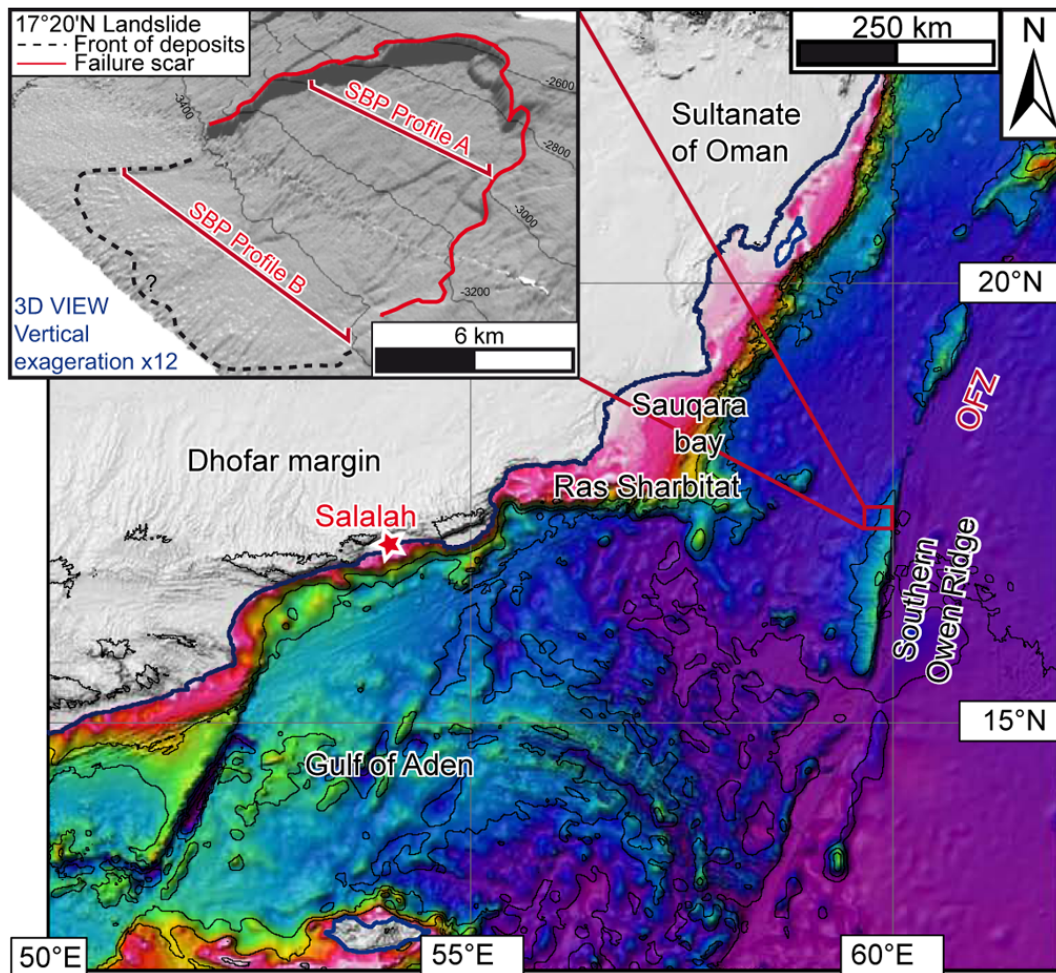

Fig. 1. Regional topographic map of the Sultanate of Oman and the offshore Owen Fracture Zone. Inset shows a 3-D view of the 17°20'N landslide located on the Owen Ridge. OFZ: Owen Fracture Zone.

al., 2012). The southern segment of the Owen Ridge displays the most voluminous landslides, including two landslides that removed up to 40–45 km³ of sediment according to their failure morphology (Rodríguez et al., 2012). To date, there are neither historical witnesses of a tsunami nor tsunami deposits on the Oman coast that can be related to a mass-wasting episode over the Owen Ridge (Pilarczyk et al., 2011; Hoffman et al., 2013). In contrast with sub-aerial or shallow landslides (Fritz et al., 2009; Mohammed and Fritz, 2012), the tsunami hazard associated with deep-sea (> 2000 m) landslides remains poorly investigated (Lo Iacono et al., 2012). The objective of this paper is to assess the severity of this potential source of tsunami hazard along the nearby Oman coasts, by modelling the generation, propagation, and heights from tsunamis triggered by the biggest submarine landslide (located at the latitude of 17°20'N) on the southern segment of the Owen Ridge.

2 Geological background and description of the 17°20'N submarine landslide

The Owen Ridge is composed of three distinct bathymetric highs running parallel to the Owen Fracture Zone, including the 300 km-long, 50 km-wide, and 2000 m-high asymmetric southern Owen Ridge (Fig. 1). The southern Owen Ridge is covered by a ~ 500 m thick pelagic drape, mainly made up of nanno-fossil ooze and clays (Shipboard scientific party, 1989). The regular western slope of the Owen Ridge, corresponding to sedimentary beds gently tilted 2–3° to the west, favours the occurrence of large retrogressive slumps with 25 events mobilizing more than 1 km³ of sediments observed on the seafloor (Rodríguez et al., 2012). The relative arrangement of slope failures and mass transport deposits along the southern ridge reveals that each slide occurred as a distinct event. Stratigraphic studies document sporadic mass wasting events through time since the uplift of the Owen Ridge in the Miocene, with a typical recurrence rate of the

Fig. 2. 3.5 kHz echo-sounder profiles (SBP 120) across the 17°20'N landslide. See Fig. 1 for location. Vertical exaggeration x28.

order of 10^5 – 10^6 yr (Rodriguez et al., 2012). The recurrence rate is determined by converting into time the thickness of pelagic deposits lying between successive mass transport deposits according to sedimentation rates calculated at ODP sites (Shipboard Scientific Party, 1989; Rodriguez et al., 2012). The seismicity along the Owen Fracture Zone is rather low and scattered (Quittmeyer and Kafka, 1984; Gordon and DeMets, 1989; Fournier et al., 2001), the maximum magnitude recorded to date being a $M_w = 5.3$ earthquake (Harvard CMT, 7 April 1985). However, millennial large earthquakes ($M_w \sim 7$) are expected (Fournier et al., 2008; Rodriguez et al., 2012) as reported at other oceanic fracture zones. Although earthquakes are the most likely triggering factor of slope failure, the apparent discrepancy between earthquake frequency and mass wasting frequency highlights the dominant control of slow pelagic sedimentation rates and hence, time needed to return to a mechanically unstable pelagic cover (Rodriguez et al., 2012).

Because the speed of the failed mass strongly affects the amplitude of the out-going wave (Trifunac and Todorovska, 2002), it is important to determine the kinematics of the landslide, i.e., whether the mass movement is a slump or a debris flow. Based solely on multibeam bathymetry and echo-sounder data, it is ambiguous to solve the latter problem as mass movement type is usually assessed by rigorous core

analyses (Mulder and Cochonat, 1996; McAdoo et al., 2000; Tripanas et al., 2008). Nevertheless, mapping the architecture of sediment failures using subsurface data provides fundamental constraints on numerical models of tsunami generation (Tappin, 2010).

The landslide located at 17°20'N is the biggest landslide (volume = 40 km^3) that occurred along the southern Owen Ridge (Fig. 1) (Rodriguez et al., 2012). In this area, the failure initiates at 2000 m water depth, and a 400 km^2 area of hummocky seafloor, characterised by a chaotic facies on echo-sounder profiles (SBP120), is partly enclosed by a 35 km-long arcuate failure scar (Figs. 1, 2). This description of the 17°20'N failure suggests a sedimentary material remaining close to the slide scar and hence a cohesive motion of the transported mass (such as in slump processes) rather than a disintegrative motion (such as in debris flow processes). Consequently, we modelled the 17°20'N landslide as a homogeneous visco-plastic flow subjected to gravity. The age of the 17°20'N landslide can be roughly inferred by converting into time the thickness of pelagic deposits that blankets mass transport deposits downslope (Fig. 2). By taking into account sedimentation rates of the order of 40 m Myr^{-1} (Shipboard scientific party, 1989), the $\sim 5.4 \text{ m}$ thick pelagic cover indicates an age for the 17°20'N deposits around 130 kyr.

3 Methods

3.1 Multi-beam bathymetry

Multi-beam bathymetry was collected using a hull-mounted Kongsberg-Simrad EM120 multi-beam echosounder during the OWEN 2009 survey onboard the French R/V *Beautemps-Beaupré* (Fournier et al., 2011). The vertical resolution of the swath bathymetric data is of the order of 10 m. The dataset allows the production of maps at a 80 m grid interval. It was combined with the SRTM grid at 30'' to produce a uniform digital elevation model (DEM) at 1 km grid spacing (datum: WGS 84). The DEM was then used for the source sensitivity studies and to investigate the impact of landslide-generated tsunami on the Arabian Sea coasts. Although the DEM includes the coastline, it is however not refined in its shallowest bathymetric part and in the first emerged meters. Thus the only estimations provided in the following consist of maximum water heights close to the coast, but do not provide any detailed mappings of flooding.

3.2 Landslide modelling

We use the AVALANCHE code that has been described in details and successfully tested for the 1998 Papua New Guinea event (Heinrich et al., 2001) and the 1979 Nice event (Labbé et al., 2012). The model is based on the shallow water assumption, with slide thickness much smaller than its length and width. This approach allows us to ignore the exact mechanical behaviour within the flow (Savage and Hutter, 1989). The mechanism initiating the landslide is not investigated in this study and it is assumed that the whole mass suddenly loses its equilibrium and begins to flow down the slope. Modelling the 17°20'N landslide as a viscous flow requires a parabolic profile of the slope-parallel velocity of the sedimentary mass, with a no-slip condition at the sea bottom (Jiang and Leblond, 1992). The shear stress $\tau_{xz}(z=0)$ at the sea bottom is expressed as

$$\tau_{xz}(z=0) = -3\mu \mathbf{u} / h\rho_s$$

where μ is the dynamic viscosity, \mathbf{u} the slide velocity, h the slide thickness perpendicular to the slope, and ρ_s the sediment density.

As viscous flows never stop on the sea bottom whatever the viscosity coefficient, it is necessary to model the 17°20'N landslide as a visco-plastic fluid (also called a Bingham plastic fluid). In a visco-plastic fluid, no deformation takes place until a specified shear stress, called the yield stress, is applied to the fluid. Above the yield stress, the material flows like a viscous fluid (Jiang and Leblond, 1993). By considering that equations are averaged through the thickness of the slide, the Bingham model requires two systems of equations to be solved, corresponding to two distinct zones in the flow, a shear flow driven by viscosity and a plug flow above it with a uniform velocity profile (Jiang and Leblond, 1993). Since

the slide thickness (140 m at the initiation) is much smaller than the slide length in the case study, the Bingham model can be simplified by considering a single layer whose motion is initiated and driven by viscosity when the shear stress exceeds a given yield stress (Norem et al., 1991; McEwen and Malin, 1989). The resulting equations of mass and momentum conservation, written in a coordinate system linked to the topography, read (see Heinrich et al., 2001)

$$\begin{aligned} \frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(h\mathbf{u}) + \frac{\partial}{\partial y}(hv) &= 0 \\ \frac{\partial}{\partial t}(h\mathbf{u}) + \alpha \frac{\partial}{\partial x}(h\mathbf{u}\cdot\mathbf{u}) + \alpha \frac{\partial}{\partial y}(h\mathbf{u}\cdot v) \\ &= -\frac{1}{2}\kappa \frac{\partial}{\partial x}(gh^2 \cos\theta) + \kappa gh \sin\theta_x - \tau_{xz}(z=0) \\ \frac{\partial}{\partial t}(hv) + \alpha \frac{\partial}{\partial x}(hv\cdot\mathbf{u}) + \alpha \frac{\partial}{\partial y}(hv\cdot v) \\ &= -\frac{1}{2}\kappa \frac{\partial}{\partial y}(gh^2 \cos\theta) \\ &+ \kappa gh \sin\theta_y - \tau_{yz}(z=0), \end{aligned}$$

where $\kappa = 1 - \rho_w/\rho_s$, $\tau_{xz}(z=0)$ and $\tau_{yz}(z=0)$ are the shear stresses at the bed surface, $\mathbf{u} = (u, v)$ is the depth-averaged velocity vector parallel to the bed, h is the slide thickness perpendicular to the slope, ρ_w and ρ_s are the water and sediments densities with a ratio $\rho_w/\rho_s = 2$, $\theta(x, y)$ is the local steepest slope angle, θ_x and θ_y are the slope angles along x - and y -axes, respectively. Values of α that deviate from unity provide information about the deviation of the slope normal profile of (u, v) from uniformity. These hyperbolic equations are solved in the same numerical scheme as the one used in the tsunami model.

3.3 Tsunami modelling

Simulations of the tsunami waves are based on the shallow-water approximation, which deals with the full interaction of landslide and water, including the deformation of the sediment body. Equations governing the landslide and the tsunami propagation are similar and non-dispersive. They are thus solved using the same Godunov-type scheme, extended to second order by using the concept of Vanleer (Alcrudo and Garcia-Navarro, 1993; Mangeney et al., 2000), which is based on a shock-capturing method originally derived from gas dynamics models (Heinrich et al., 2001). This model is particularly adapted to deal with nonlinear waves. The sea bottom deformation through time resulting from the landslide motion is introduced as a known forcing term $(\cos\theta)^{-1} \partial h / \partial t$ in the mass conservation equation of the tsunami model. Finally, our model also allows the computation of inundation (run-up) heights at the receiving shore.

4 Results

Several sensitivity tests of parameters were performed. The major parameter controlling tsunami generation is the cohesion of sediment within the flow, tsunami being generated

for cohesion less than 40 g m^{-3} . Simulations have been carried out for dynamic viscosity values ranging between 25 and 500 m s^{-2} , consistent with observations of subaerial debris avalanches (Sousa and Voight, 1991, 1995). For a fixed cohesion value, the dynamic viscosity of the flow has no significant impact on the slide motion and therefore on the wave field pattern. Values of dynamic viscosity ranging between 250 and 500 m s^{-2} better reproduced the observed extension of mass transport deposits. About 400 s after slide initiation, the resulting average velocities of the landslides reach $\sim 40 \pm 3 \text{ m s}^{-1}$.

At the source location, the original radiated wave is formed of two peaks and one trough. The water ahead of the front face of the slide is pushed away, creating a leading positive wave in the slide direction. The trough following the crest is simultaneously created by the slide excavation, and is followed by a large second positive peak created by the infilling of the trough (Fig. 3). In spite of the $\sim 2000 \text{ m}$ water depth of slide initiation, water heights at the source can reach 4.8 m in elevation, the highest waves being formed in the out-going direction of the slide, thus towards the Oman coast. Amplitudes of the back-going waves are reduced and significantly attenuated only 8 km east from the source. The three out-going waves spread away from the source as cylindrical waves (Fig. 3). The tsunami wave field mainly affects Oman coasts, other areas being too far from the source. The time for the first leading wave to reach the Oman coastline at Ras (cape) Madrakah is 35 min (Fig. 3). The complex bathymetric pattern related to the transition between the Oman transform margin (between 18°N and $22^\circ30'\text{N}$) and the rifted margins of the Gulf of Aden strongly influences the propagation of the tsunami wave field (Figs. 1, 3). Indeed, Hasik town and Salalah city are impacted by the tsunami 43 and 60 min after the submarine failure, respectively, whereas Ras Sharbitat, closer to the tsunami source, is impacted after 80 min of tsunami propagation (Fig. 3). This delay is due to the $\sim 120 \text{ km}$ wide continental shelf at the latitude of Ras Sharbitat, which slows down the propagation of the tsunami. Because of reduced continental shelves, the coastlines of the eastern Gulf of Aden are impacted earlier.

In order to investigate the behaviour of tsunami waves obtained for the maximum scenario, we plot the maximal water heights reached after a 2 h propagation time in the whole computational domain (Fig. 4). This map indicates the spatial distribution of the tsunami energy along Oman coastlines and reveals additional bathymetric forcing. First, numerous canyons that dissect the slope between 18° and 20°N locally amplify the wave elevation up to 2 m. Second, the Sharbitat Ridge, which is an E–W rectilinear, $\sim 140 \text{ km}$ -long submarine extension of the Oman margin located at the entrance of the Gulf of Aden, strongly influences the tsunami propagation and amplifies wave elevation up to 6 m (Fig. 4). The most affected area is the Sauqara Bay (between 18° and 19°N) with water heights reaching 2.5 m at the coastline, locally 4 m in the vicinity of Ras Sharbitat. Locally, tsunami waves

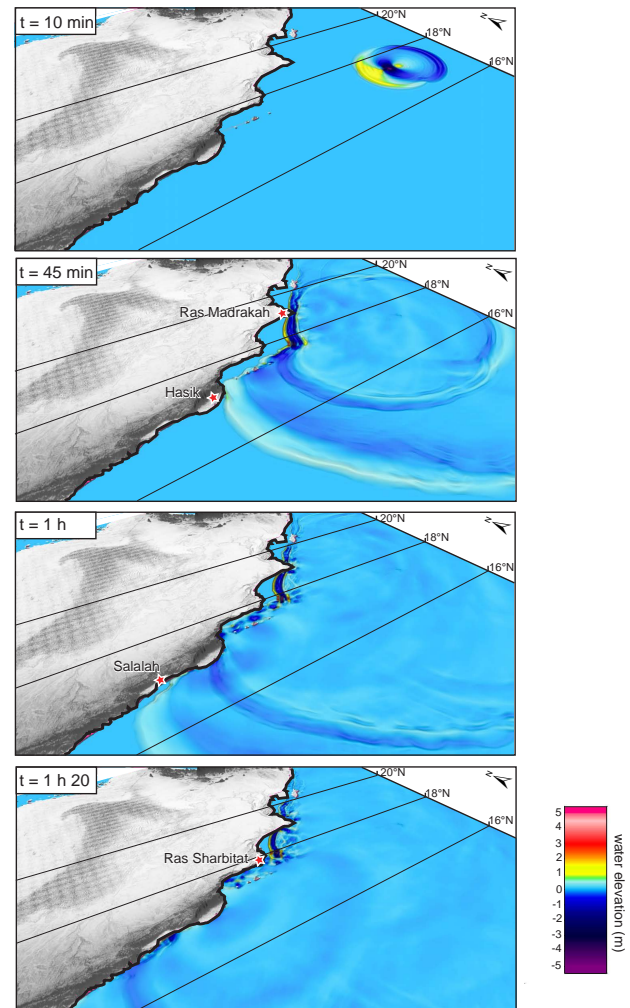

Fig. 3. Snapshots of the computed water surface for a dynamic viscosity value at 500 m s^{-2} . Vertical scale is exaggerated by a factor of 20 with respect to horizontal scale.

on the order of 1 m impact the coastline of the Masirah Bay. Run-up values of $\sim 2 \text{ m}$ are calculated at Salalah, the most populated city of the area.

5 Discussion and conclusions

Numerical results show that a submarine landslide similar to the one that occurred at $17^\circ20'\text{N}$ on the Owen Ridge can produce moderate tsunamis along the Oman east coast. Such tsunamis would impact industrialised but low populated areas, except for the city of Salalah (190 000 inhabitants) in the Gulf of Aden and the newly built Port of Duqm on the east Oman coasts. Maximum calculated wave height values along the east Oman coasts would be of the same order as run-up values reported for the 2004 Indonesian transoceanic event for the same coasts (0.7 to 3.3 m) (Okal et al., 2006; Okal and

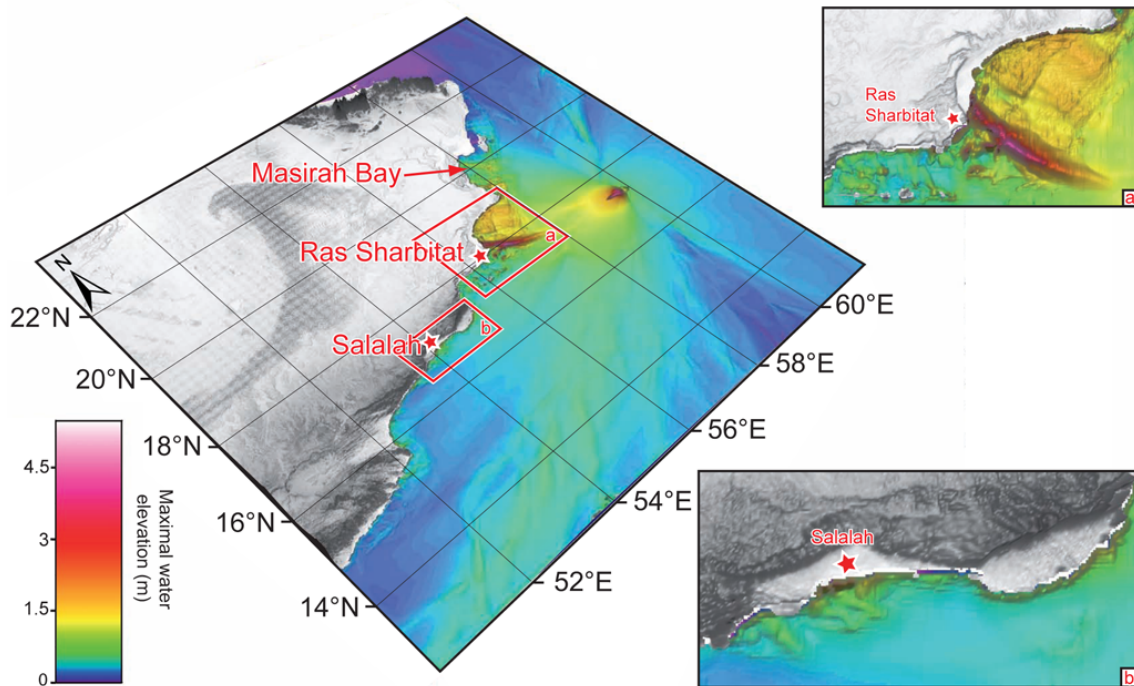

Fig. 4. Maximum water elevations computed after a 8000 s simulation for a dynamic viscosity value at 500 m s^{-2} . Insets show the maximum water elevations computed around Ras Sharbitat (inset a) and Salalah (inset b).

Synolakis, 2008), and stronger than amplitude values calculated for the 1945 Makran event ($< 0.4 \text{ m}$) (Okal and Synolakis, 2008).

As already explained earlier, the modeled tsunami height values obtained with a 1 km cell size are not strictly run-up values since the flooding is not modeled, and they would be probably amplified using refined bathymetric grids close to the coast due to the tsunami shoaling effect which is all the more well accounted for as the grid spacing is lower. Depending on the local bathymetric slopes and configuration, these waves may locally be greatly amplified and yield amplitudes above 3 m at least. Another source of uncertainty is the non-dispersive numerical model that is not able to account for frequency dispersion inherent in tsunamis with short wavelengths, thus especially for landslide triggering. However the large extent of the $17^{\circ}20' \text{ N}$ landslide probably precludes a strong influence of frequency dispersion, specially because the wavelengths considered here are not so short with respect to the water depth, and also because the distance of propagation is not large enough to offer a significant effect of this dispersion. On the other hand, amplitude dispersion may locally occur on the continental shelf (Geist et al., 2009) and especially near Ras Sharbitat, leading to relatively attenuated wave heights in this area.

Other submarine landslides identified off Salalah on the Dhofar margin (Fig. 1) (Bache et al., 2010) may potentially be a more important source of tsunami hazard in the area.

This study further demonstrates that submarine landslides occurring along remote and deep oceanic ridges (only blanketed by pelagic material) can be a source of infrequent but quite significant tsunamis. The present-day state of slope stability along the Owen Ridge remains unknown, and it is difficult to assess if a voluminous landslide is bound to occur in the near future. Other places in the world are potentially vulnerable to this type of tsunami sources. For instance, in the Atlantic Ocean, the Gorringer Bank rock avalanche (Zitellini et al., 2009), which is $60\text{--}80 \text{ km}^3$ in volume and 26–30 kyr old, could have generated a potentially destructive tsunami on densely populated Portuguese, Spanish (Lo Iacono et al., 2012) and Moroccan coastlines. In contrast with the numerous large landslides observed along the Owen Ridge, the Gorringer Bank rock avalanche is the only large landslide ($> 1 \text{ km}^3$) observed along the Gorringer Bank since its Miocene uplift (Jiménez-Munt et al., 2010), which is conspicuous with regards to the high frequency of large magnitude earthquakes ($M_w > 6$) in the area (Baptista and Miranda, 2009). This contrasts with slope failures on the nearby Portuguese margin that produced turbiditic deposits whose estimated ages correlate well with the most important historic earthquakes and tsunamis (Gràcia et al., 2010). This comparison suggests that conditions for a large slope failure to occur along the Gorringer Bank might bring together a sufficient volume of sediment (limited by slow pelagic sedimentation rates) and a favourable state of consolidation. The

state of slope stability of remote oceanic ridges similar to the Owen Ridge or the Goringe Bank needs to be further investigated, but the overall return periods of such deep-sea seated tsunamigenic instabilities are not expected to be less than several thousands of years.
