Analysis of Dissolved Gases by Headspace Sampling Gas Chromatography With Column and Detector Switching. Preliminary Results

Pierre-Marie Sarradin and Jean-Claude Caprais
IFREMER Centre de Brest, DRO/EP, BP 70, 29280 Plouzane, France

This preliminary study presents a new method for the determination of dissolved gases in sea-water. After headspace extraction, gaseous compounds are separated by GC on a dual column adsorption system. The individual species are thereafter eluted to three different detectors (thermal conductivity, flame ionization and FPD) using a second switching valve. The analysis is quantitative for methane and carbon dioxide with limits of determination of 0.1 and 50 μmol l⁻¹, respectively, and corresponding standard deviations of 4 and 7%, and has been applied to deep sea hydrothermal samples. Further optimization is necessary to allow the quantitative determination of hydrogen sulfide, nitrogen, oxygen and carbon monoxide.

Deep sea hydrothermal vents are characterized by the presence of hot fluid sources with unusual chemical compositions, i.e., high temperature, low pH, high sulfide and methane concentrations. Particular ecosystems are associated with these vents. In the absence of light, these are based on chemosynthesis and carbon monoxide.

Cold sea-water. Present in the fluid are the dissolved gases CH₄, H₂S and CO₂ (Table 1).

In this study, sampling was carried out using a sampler deployed from the French deep-sea submersible research vessel Nautile. Samples were difficult to obtain and had to be handled with care as other analyses were carried out on the 150 ml of water.

The objective of this study was to develop a method for the determination of dissolved gases in a minimum volume of water, with a single shot and a good working range. The first part of this work focused on CH₄, CO₂ and H₂S. Table 2 presents the analytical methods generally used for the analysis of each compound.

The only method existing for the simultaneous determination of CH₄, CO₂ and H₂S is the method of Childress et al. for the determination of high concentrations of these gases in blood. This procedure can be divided into three steps: extraction of the gases from water, separation and detection.

The purge and trap method seems to be the most efficient method for the extraction of CH₄, CO₂ and H₂S, because of the enrichment step. However, several unsuccessful attempts were made by us to simultaneously cryotrap CH₄, CO₂ and H₂S. The experiments were carried out using packed glass columns with different packing materials, the cryogen being liquid nitrogen. Childress et al. used an acid stripping method (dynamic headspace without trapping) in a purpose-built reactor; this method is only available for concentrated samples (blood) and small injection volumes.

An alternative method is headspace sampling which has a good working range for CH₄ and CO₂. This method was tested for the complete set of gases.

The complete chromatographic separation of CH₄, CO₂ and H₂S is not possible on a single column. A dual column system with a switching valve must be used. The first column used in the study of Childress was a Poraplot Q: this separated O₂, N₂, CO and CH₄ as a single peak from CO₂, H₂S and water. The first peak (O₂, N₂, CO, CH₄) was trapped on the second column.

(molecular sieve), the valve was switched and CO₂, H₂S and water were eluted directly to the detectors. When the elution was finished on the Poraplot column, the final separation of O₂, N₂, CO, CH₄ was carried out on the molecular sieve after a second valve switching.

Childress et al.⁹ used a thermal conductivity detector (TCD) for the detection of the gases. To improve sensitivity more specific detectors were used in this study: a TCD for CO₂, N₂, CO, O₂, a flame ionization detector (FID) for CH₄ and an FPD for H₂S. Species were eluted to the different detectors using a second switching valve.

Experimental
A schematic diagram of the complete analytical device used is presented in Fig. 1.

A preliminary study was carried out using 20 ml headspace flasks, with a 10 ml sample of water and 0.1 ml of 6 mol l⁻¹ hydrochloric acid under He. The flask was heated for 30 min at 70 °C under stirring. The injected headspace volume was 2.5 ml. To reduce the analysis time, a temperature programme was used [40 °C (held for 7 min); raised at 15 °C min⁻¹ to 130 °C (held for 13 min)].

The headspace sampler used was a DAN1 HSS 86-50 with a Silicostil heated transfer line. The separation was performed using a series 8000 Fisons gas chromatograph equipped with a TCD, an FID El 980 and an FPD and LIN 700 (linearizer). The switching valves were made of Hastelloy (Valco). The columns and pressure drop were Chrompack Poraplot Q Ultimetal 0.53 mm, 25 m and Molecular sieve 5A Plot Ultimetal, fused silica 0.32 mm, 5 m. The carrier gas was He N55 (0.49 bar). The integration software was Borwin 4 channels. Calibration was achieved either with a standard gas mixture from Scotty with Hamilton gas-tight syringes 1700 RN series or with standard solutions of sodium sulfide nonahydrate (Rectapur, Prolabo) and sodium hydrogen carbonate (pro analyti, Merck).

Results and Discussion
Fig. 2 presents a chromatogram obtained with this method for concentrations of 35 pmol l⁻¹ of H₂S, 200 pmol l⁻¹ of CO₂ and 120 µmol l⁻¹ of CH₄. The valves were switched at 315 s (E1), 440 s (E2) and 14 min (E1, E2). The chromatographic resolution enabled qualitative analysis. However, the baseline for the TCD was disrupted by the temperature programme. The use of an isothermal temperature program or a mass flow controller would cancel this problem.

Fig. 3 presents the calibration curves for the three compounds, obtained by the liquid addition of Na₂S and NaHCO₃ and gaseous addition of CH₄ to 10 ml of sea-water. The low sensitivity for H₂S may be due to the adsorption of sulfide on part of the gas chromatograph, although most of the inox parts had been replaced except for the syringe needle of the headspace.

![Fig. 2](image2.png)  
**Fig. 2** Chromatogram obtained for a mixture of Na₂S (35 µmol l⁻¹), CO₂ (200 µmol l⁻¹) and CH₄ (120 µmol l⁻¹).
The determination limits (3 × noise integration/calibration slope) were 0.1 and 50 μmol l⁻¹ for CH₄ and CO₂, respectively. Standard deviations (n = 5) were 4% for 80 μmol l⁻¹ of CH₄ and 7% for 800 μmol l⁻¹ of CO₂.

**Application**

The analytical device described here has been used aboard the French oceanographic vessel ‘Nadir’ during the HOT 96 diving cruise undertaken by IFREMER CNRS Marine Research Unit no. 7 on the 9° and 13° N hydrothermal sites of the East Pacific Rise. Fifty water samples were collected of the various organisms present (Riftia, Alvinellids and mussels) by the French submersible Nautile using a specific vacuum-based and gas-tight sampler. Hydrogen sulfide was not quantified because of its low sensitivity. For methane and carbon dioxide concentrations of 1–5 μmol l⁻¹ (sea-water 0 μmol l⁻¹) and 900–8000 μmol l⁻¹ (sea-water 2280 μmol l⁻¹) were determined, respectively.

**Conclusions**

The headspace extraction conditions (temperature, time, pressure) must be further optimized to improve the efficiency and to reduce the amount of water injected. The hydrogen sulfide line must be checked to eliminate the possible remaining inox parts and to study the working conditions for the FPD (air and H₂ amount in the flame) to enhance the sensitivity. The concomitant use of a TCD and a temperature program led to a fluctuating baseline use of a flow controller may overcome this problem. This preliminary study has focused on the analysis of CH₄, H₂S and CO₂. Future work will involve the quantitative determination of O₂, N₂ and CO using the same method.
