Abstract :

Ferromanganese (Fe-Mn) deposits constitute a ubiquitous mineral type in oceanic settings, with metal (Cu, Ni, Zn, Co, Pt) and rare earth elements (REE) enrichments of potential economic interest. Routine analysis of trace elements by ICP-MS has advanced our understanding of the impact of hydrogenetic, diagenetic and hydrothermal processes on the mobility and interaction of high field strength elements (HFSE: Zr, Ti) and REE and yttrium (REY) with Fe-Mn oxyhydroxides. Recent discoveries in the French exclusive economic zone (EEZ) of Wallis and Futuna (southwest Pacific Ocean) have brought new insight to the formation of low temperature (LT) hydrothermal Mn deposits and lead us to reconsider the classification and discrimination diagrams for of Fe-Mn deposits and ore-forming processes. Using a suite of LT hydrothermal Fe-Mn crusts from Wallis and Futuna, we investigate how contrasting genetic processes influence the distribution of metals (Mn, Fe, Cu, Ni, Co), HFSE and REY in hydrogenetic, diagenetic, hydrothermal and mixed-type deposits from different environments in the global ocean. The interaction of the different metal oxide-forming processes indicates that: (i) enrichment of Co, HFSE and REY is favored by hydrogenetic precipitation, (ii) diagenetic processes produce higher Mn, Cu, and Ni concentrations with oxic remobilization in the sedimentary column, while suboxic conditions promote greater Mn and Fe remobilization that competes with the incorporation of Cu and Ni ions in nodules. HFSE and REY derived from seawater are usually low in diagenetic precipitates, which discriminate between hydrogenetic and diagenetic inputs within nodules, (iii) hydrothermal Fe-Mn deposits show strong depletion in HFSE and REY due to rapid formation and high contents of either Fe or Mn oxides. We present a new discrimination scheme for the genetic types of Fe-Mn deposits using a $10^*(Cu + Ni + Co) - 100^*(Zr + Y + Ce) - (Fe + Mn)/4$ ternary diagram. The use of HFSE and REY in the classification allows for a more robust discrimination of: (i) each ore-forming process with well-delimited fields, without overlap of metal-rich hydrothermal samples and hydrogenetic samples, (ii) oxic and suboxic diagenesis within nodules, (iii) trends between hydrogenetic and diagenetic end-members forming a continuum, (iv) mixed genetic types such as the presence of hydrothermal particles within hydrogenetic crust layers. Alternatives are also explored to adapt our discriminative diagram to elements measurable by on-board instruments to aid in exploration at sea.

Graphical abstract

Ternary diagram presenting the classification scheme and delimited areas for each genetic process involved in the formation of oceanic ferromanganese mineralizations using HFSE and REE data. The dotted arrows present the mixing trends between two genetic processes highlighting the continuum existing between hydrogenetic-hydrothermal crusts and hydrogenetic-diagenetic nodules. Solid arrows show evolution trends of a sample set related to only one genetic process without influence of another one.

Highlights

► Discovery of metal-rich, low temperature hydrothermal deposits in South Pacific Ocean ► Inability to fit in previous classification due to abnormal high metal content ► Satisfying discrimination obtained combining REE and HFSE with Mn, Fe, Cu and Ni ► New discrimination scheme is proposed for oceanic Fe-Mn deposits. ► Detailed relations highlighted between the various genetic processes

Keywords : Ferromanganese mineralization, hydrogenetic crusts, nodules, hydrothermal deposits, rare earth elements, high field strength elements, classification

1. Introduction

Ferromanganese (Fe-Mn) deposits reflect common forms of mineralization in the modern ocean. They may contain significant metal (Cu, Ni, Zn, Co) and rare earth elements plus yttrium (REY) enrichments. Oceanic Fe-Mn deposits include ferromanganese crusts, also referred as cobalt-rich crusts, polymetallic nodules, and hydrothermal crusts and impregnations. Numerous reviews of Fe-Mn deposit genetic processes and distributions exist [Halbach et al., 1981; Aplin and Cronan, 1985; Halbach et al., 1988; Hein et al., 1997; Hein et al., 2000; Hein and Koschinsky, 2013; Hein et al., 2013]. These deposits are classified in three main categories: hydrogenetic, diagenetic and

hydrothermal [Bonatti *et al.*, 1972; Hein *et al.*, 1997; Bau *et al.*, 2014; Schmidt *et al.*, 2014] and are commonly discriminated by using characteristic variations of Fe, Mn, Cu, Ni, and Co contents.

Crusts form by hydrogenetic precipitation of colloidal particles of Fe and Mn oxyhydroxides onto rock substrates [Dymond *et al.*, 1984; Bau *et al.*, 1996; Hein *et al.*, 2000; Schultz, 2006]. Hydrogenetic crusts concentrate some trace metals (Co, Ni, Ti, HFSE and REY) at many orders of magnitude above their concentration in seawater [Bau *et al.*, 1996; Hein and Koschinsky, 2013], which is promoted by high reaction surface area of Fe-Mn oxyhydroxides (average of 325 m²/g for bulk δ -MnO₂ and FeOOH) [Hein and Koschinsky, 2013; Pourret and Davranche, 2013], slow oxidation reaction kinetics, and slow growth rates [Bau *et al.*, 1996]. Polymetallic nodules constitute mixed-source deposits formed by hydrogenetic and/or diagenetic precipitation of Fe-Mn colloids around a nucleus on the surface of soft sediments. Interactions of both hydrogenetic and diagenetic processes lead to a range of bulk Mn/Fe ratios from 1 to 2.5 for oxic diagenesis and up to 50 when the sedimentary column is suboxic near the seabed [Calvert and Piper, 1984; Schultz, 2006]. Metals (Ni, Cu, Co), REY and HFSE in nodules are mainly derived from seawater through hydrogenetic precipitation and further enrichment in metallic elements (Mn, Cu, Ni and Zn) occurs via diagenetic precipitation [Ohta *et al.*, 1999].

Hydrothermal Fe-Mn deposits form under various conditions of temperature and geological settings; (i) plume fall-out deposits associated with high temperature venting [Bonatti, 1975; Corliss *et al.*, 1978; Barret *et al.*, 1987; German *et al.*, 2002] form when particles derived from hydrothermal solutions precipitate during mixing with cold oxidizing seawater and settle on the seafloor forming the well-known metalliferous sediments encountered near hydrothermal fields such as along the East Pacific rise (EPR) or the Mid-Atlantic Ridge (MAR) [Barret and Jarvis, 1988; Goulding *et al.*, 1998]. Enrichment of metals, REY and other critical elements in oxyhydroxides occurs by sorption from seawater onto colloids in seawater and on the surface of crusts and nodules after accretion of the colloids. (ii) Diffuse hydrothermal systems are usually associated with off-axis hydrothermal circulation along MOR and within submarine volcanoes along volcanic arcs and hot spot seamounts, or less commonly associated with fractures distant from oceanic ridges [Hein *et al.*, 2008b; Edwards *et al.*, 2011]. They form stratabound layers, crusts, and cement the sediment column with either Fe or Mn oxides by fluids percolating within porous sediment, pyroclastic deposits, and volcanic breccias [Fouquet *et al.*, 1993]. These deposits show a distinct mineralogy and texture from hydrogenetic crusts [Burgath and Von Stackelberg, 1995; Schultz, 2006]. Fe-Mn hydrothermal deposits exhibit a wide range of Mn/Fe ratios from 0.001 (nearly no Mn) up to 4,000, as a function of fluid temperature and redox conditions [Burgath and Von Stackelberg, 1995; Schultz, 2006]. The rapid precipitation of these hydrothermal oxides commonly forms deposits with low minor metal contents; those influenced by hydrogenetic precipitation show an intermediate composition.

In 2010 an Ifremer mission exploring the mineral resources potential of the Wallis and Futuna archipelago (SW Pacific) dredged Fe-Mn hydrothermal samples showing the strongest metal enrichments recorded in Fe-Mn oceanic deposits [Pelleter *et al.*, 2016]. Hence the discovery of these metal-rich low temperature (LT) hydrothermal deposits requires explanation of (i) their mode of formation, (ii) the associated fluid geochemistry, and (iii) their economic potential as an oceanic resource, as well as (iv) the way we classify and discriminate Fe-Mn oceanic Fe-Mn deposits. Although we present bulk geochemical and mineralogical results for these unusual deposits, the first questions are presented elsewhere [Pelleter *et al.*, 2016]. We develop here how these deposits

challenge our way of classifying Fe-Mn oceanic deposits and explore new geochemical tools for their discrimination.

2. Material and methods

2.1. Material

Hydrothermal samples were recovered during an Ifremer research cruise in the French exclusive economic zone (EEZ) of Wallis and Futuna in August 2010. The area studied is bordered by the North Fiji fracture zone, the active Tonga and Vanuatu subduction zones and associated Lau and North Fiji back-arc basins, and the currently active Samoan hotspot. Several extensional zones were recognized [Pelletier *et al.*, 2001; Fouquet *et al.*, 2015] including the Futuna and Alofi ridges and an area formed by a complex system of diffuse magmatism with multiple volcanic edifices. Three atypical low-temperature Fe-Si-Mn deposits were discovered during the cruise aboard R/V Atalante, Utu Uli, Anakele, and Utu Sega (Figure 1) from which samples were collected by dredging and HOV dive operations. The deposits found at Utu Uli and Anakele occur as massive, dense and laminated crusts of Mn oxyhydroxides from the summit of volcanic edifices composed of pyroclastic material, pillow lavas and more rarely sediments. Locally, the Mn crusts are crosscut by Fe-Si precipitates displaying ridge or vein-like structures up to 1 m high [Pelletier *et al.*, 2016]. The mineralization extends below these crusts as Mn oxyhydroxides, Fe oxides and nontronite cementing basaltic pyroclastic facies and brecciated lavas [Pelletier *et al.*, 2016]. Crusts have been observed covering three distinct volcanic edifices in the Utu Uli area representing an approximate area of 1.5 km² with thicknesses up to 5 cm, whereas sediment accumulation at the other sites prevented estimation of the extent of the deposits. No hydrothermal discharge was observed in the vicinity of the three sites. The present study focuses on 16 samples recovered from dredge hauls showing a range of composition from nearly pure Mn oxide to mixed Mn-Fe ± Si compositions. Sample FU-DR01-03 was later subdivided in three subsamples of oxides from the impregnated host sediment, an internal layer of the crust and the surface layer. See Pelletier *et al.* [2016] for bulk composition.

2.2 - Methods

Mineralogical identification was made through X-ray diffraction (XRD) at Ifremer using a BRUCKER AXS D8 Advance (with Bragg-Bentano goniometer and VANTEC-1 positive sensitive detector -PSD and BRUCKER AXS D2 Phaser. Prior to analysis, samples were dried at 60°C and milled with agate mortar then deposited on a XRD sample holder and flatten with a glass slide. Samples were analyzed using Cu-K α radiation over 2 θ ranging from 2° to 70° at 40 kV and 30 mA. Additional analyses were made to characterize clay minerals [Pelletier *et al.*, 2016]. Minerals were identified using Eva search-match software.

Bulk chemical composition of each sample was determined. Samples were ground to a powder (90% of particles < 80 μ m) using an agate pestle and mortar. Major elements and selected trace elements

were analyzed by X-ray fluorescence with a BRUCKER AXS S8 Tiger automated XRF spectrometer on pressed pellets [Pelleter *et al.*, 2016].

Additional trace elements (Sr, Y, Zr, Nb, Th, REE) were analyzed by inductively coupled plasma mass spectrometry using an ELEMENT II magnetic field ICP-MS at Institut Universitaire Européen de la Mer (IUEM) in Brest. The dissolution procedure was as follows; 0.1 g of sample powder was digested in a Teflon bottle with 4 mL of 6 mol/L hydrochloric acid for 24 h on a hot plate (120°C) with a Tm spike. If present, the residual phase composed of mostly silicates and refractory minerals was then extracted by centrifuge and digested by a mixture of hydrofluoric and hydrochloric acid (3:1) for 48 h on hot plate (120°C), evaporated and then remixed with the previously digested phase. The solution (0.5 µL) was then evaporated on a hot plate and the residue was made up to 10 mL with a 2% nitric and 0.05% hydrofluoric acid solution for trace element analysis by ICP-MS. Data were corrected using internal calibrations, BHVO-2 standard, and a Tm spike correction [Barrat *et al.*, 1996]. Concentrations are expressed as % for weight %.

The rare earth and yttrium (REY) are discussed separately from the HFSE group for ease of description of their geochemical behavior and fractionation into Fe-Mn oceanic deposits although most lanthanides are HFSE from a geochemical point of view apart for Eu in its divalent state considered a large ion lithophile element (LILE). The Ce and Eu anomalies (Ce/Ce* and Eu/Eu*) are calculated as the ratio of the normalized values (subscript n) of an element by the interpolation of the adjacent elements (superscript *) such that;

$$\text{Ce/Ce}^* = \frac{\text{Ce}_n}{\sqrt{(\text{La}_n * \text{Pr}_n)}}$$

and

$$\text{Eu/Eu}^* = \frac{\text{Eu}_n}{\sqrt{(\text{Sm}_n * \text{Gd}_n)}}$$

note that all following data of this study have been calculated using normalization to chondritic values, normalization to Post-Archean Australian Shale (PAAS, Taylor and McLennan [1985]) is used for calculation of normalized Y/Ho ratio [Bau *et al.*, 2014].

Pearson coefficient correlation matrix was calculated on the data set (n = 18) to observe correlated geochemical variations and extract information on possible phase associations during precipitation. SiO₂, Al₂O₃, Fe, Mn, CaO, MgO, TiO₂, P₂O₅, Co, Ni, Cu, Y, Zr, La, Ce, Eu, Yb, Ce/Ce*, Eu/Eu* and total REE content (ΣREE) were taken into account. As geochemical concentrations for each element do not follow a normal distribution, results are later reported as the median with a 95% confidence level.

3. Results

3.1. Mineralogy

Bulk X-ray diffraction on the massive surface layer displaying a metallic grey luster shows birnessite and todorokite, 7 Å and 10 Å manganates respectively [Pelleter *et al.*, 2016]. The presence of

vernadite (poorly crystalline δ -MnO₂) is suspected but could not be confirmed due to the overlap of reflections with birnessite and todorokite. Iron oxides are dominated by amorphous oxyhydroxides, with the presence of discrete goethite grains. Nontronite, the ferrous end-member of dioctahedral smectite, forms the cement for and replaces pyroclastic rocks onto which the Mn oxide layers developed.

3.2. Bulk Geochemistry

Bulk sample composition is dominated by Mn ($40.5 \pm 3.6\%$), SiO₂ ($3.5 \pm 2.6\%$ including 5 outliers ranging from 12.4 to 16.7%) and Fe ($3.0 \pm 2.2\%$ including 4 outliers ranging from 10 to 16.5%), with Mn/Fe ratio ranging from 1.6 to 3929 (Table 1). Other major elements decrease in abundance as follow; Na₂O ($4.4 \pm 0.4\%$), MgO ($2.5 \pm 0.4\%$), CaO ($1.75 \pm 1.0\%$), Al₂O₃ ($0.64 \pm 0.5\%$) and TiO₂ ($0.05 \pm 0.04\%$). Focus metal contents of some samples are anomalously high in comparison with typical hydrothermal Fe-Mn deposit metal concentrations [Hein *et al.*, 1997], with $0.72 \pm 0.7\%$ Ni, $0.35 \pm 0.3\%$ Co and $0.15 \pm 0.2\%$ Cu, with maximum values of 4.7% Ni, 2.2% Co and 1.5% Cu (Table 1). This enrichment in potential economic metals is unusual for LT hydrothermal deposits and suggests the absence of sulphide precipitation at depth at higher pressure and temperature conditions, which usually scavenge most of the Ni and Cu. These deposits might constitute the distal end-member of high temperature systems whereby metals were transported in a fluid with high oxygen fugacity. Continuous mixing with seawater lead to the precipitation of Fe and Mn oxides, rapidly scavenging transported metals [Pelletier *et al.*, 2016]. Other trace elements fall into the expected range of concentrations for LT Fe-Mn hydrothermal deposits; Sr (329 ± 37 ppm), Y (18 ± 4 ppm) and Zr (5.3 ± 3 ppm, excluding sample FU-DR15-06 with 85 ppm Zr).

REE concentrations in these hydrothermal samples are low (Σ REE = 26.1 ± 11.5 ppm), with a maximum content of 126 ppm REE in sample FU-DR15-06 associated with the highest concentration in P₂O₅ (0.43%) and Zr. Normalized REE trends (Figure 2) show two distinctive signatures. One group includes all samples from dredge FU-DR22, while the second group includes the rest of the hydrothermal sample set. This latter group displays marked light-REE (LREE) enrichment with regards to middle-REE (MREE); La_{CH}/Sm_{CH} varies from 2.98 to 7.02 and Gd_{CH}/Yb_{CH} ratios from 0.88 to 1.20. Most patterns display a negative Eu anomaly (0.67 – 0.98) and Ho and Er enrichment forming the top of a smooth convex-up pattern on the HREE. On the other hand, samples from core FU-DR22 have approximately flat LREE-MREE patterns (La_{CH}/Sm_{CH} = 0.83 – 1.52) with distinct heavy-REE (HREE) enrichment; average Gd_{CH}/Yb_{CH} = 0.47. A marked positive Eu anomaly is present as well as both positive and negative Ce anomalies for different samples. The Y_{PAAS}/Ho_{PAAS} ratio for these hydrothermal samples varies from 0.66 to 1.37, regardless of the REE pattern, showing a depletion in Y relative to shale for many of those samples. This signature is thought to represent precipitation of oxides from a fluid close to seawater composition [Bau *et al.*, 2014; Schijf *et al.*, 2015]. High temperature hydrothermal fluids associated with vent systems usually show well-developed positive Eu anomalies [Michard, 1989; Bau, 1991; Douville *et al.*, 1999; Craddock *et al.*, 2010]. Consequently, REE trends from Utu Sega samples (FU DRR 22) with small positive Eu* anomalies reflect a greater influence of a HT fluid than at the two other sites.

The correlation coefficients (Table 2; n = 18) can be explained in terms of mineralogical control for most major elements. Iron and Si are strongly fractionated from Mn during precipitation as Fe and Si

precipitate under slightly reducing conditions to form nontronite, or amorphous silica and Fe oxyhydroxides as highlighted by the strong correlation of Fe and SiO₂ (0.75). On the other hand, Mn forms oxyhydroxides at the seawater-sediment interface or impregnations within the volcanoclastic-sedimentary pile under oxidizing conditions, showing a negative correlation with Fe (-0.72) and Si (-0.80). Mn is negatively correlated to MgO, P₂O₅, Zr and Ce (-0.63 to -0.72). Aluminum is strongly positively correlated to TiO₂ (0.96), CaO and MgO ($r > 0.7$). Copper, Ni and Co do not show significant correlations ($-0.5 < r < 0.3$) with elements considered here and behave independently from each other in this sample set. P₂O₅ correlation with Fe (0.96) is consistent with phosphate sorption onto Fe oxyhydroxides in hydrothermal systems [Edmonds and German, 2004]. Among HFSE and REY, all are positively correlated to P₂O₅ (0.62 to 0.90), except Yb which does not show significant correlations (0.39). The total REE content (Σ REE) correlates positively with P₂O₅ and Fe (0.82 and 0.69 respectively) and not significantly to Mn (-0.48), suggesting that minor scavenging from open seawater occurred during formation of the Mn crusts with REE mainly derived from the LT hydrothermal fluids.

4. Discussion

4.1. Classification and alternatives

Fe-Mn deposits have typically been classified using the Bonatti ternary diagram [Bonatti *et al.*, 1972] using major chemical characteristics (Fe, Mn, Cu-Ni-Co) to discriminate them. Our hydrothermal samples scatter on the Mn-(Co + Cu + Ni) side of the diagram as a result of the unusual metal enrichments which places them outside of the originally identified hydrothermal field (Figure 3) [Bonatti *et al.*, 1972]. Some samples have even higher minor metal contents than the polymetallic nodules. Nevertheless, apart from the atypical Ni-Co-Cu enrichments of these deposits, samples from Wallis and Futuna are similar in composition and mineralogy to LT hydrothermal deposit collected in the Gulf of Aden [Cann *et al.*, 1977], the Mediterranean Sea [Dekov *et al.*, 2009], the Mid-Atlantic Ridge [Mills *et al.*, 2001; Severmann *et al.*, 2004] and the Pacific Ocean [Corliss *et al.*, 1978; Alt, 1988; Fouquet *et al.*, 1993; Hein *et al.*, 1996; Kuhn *et al.*, 2003; Fitzgerald and Gillis, 2006; Hein *et al.*, 2008b; Sun *et al.*, 2012; Zeng *et al.*, 2012].

In addition to the problem posed by this set of samples from the Wallis and Futuna EEZ, the ternary classification of Bonatti *et al.* [1972] does not clearly discriminate Fe-Mn deposits formed by mixed genetic processes such as nodules with various hydrogenetic/diagenetic proportions, hydrothermally derived particles incorporated during hydrogenetic crust growth, and our hydrothermal samples. The issue for nodules was discussed previously [Halbach and Puteanus, 1988] and hydrogenetic, diagenetic, and mixed-typed were identified within the existing diagram.

Alternative classification systems have been proposed and discussed recently for the discrimination of Fe-Mn deposits. Other ways have been explored using exclusively major [Conly *et al.*, 2011], or minor and trace elements [Choi and Hariya, 1992; Nicholson, 1992; Bau *et al.*, 2014]. Within a MgO*10 - Fe₂O_{3t} - MnO₂ ternary diagram, Conly *et al.* [2011] described discriminating fields for oceanic and terrestrials Fe-Mn deposits. Despite some overlaps, this diagram allows samples separation due to the use of Mg as a discriminative feature for fluid chemistry; oceanic waters containing ~1,200 ppm of Mg while end member hydrothermal fluids are considered Mg-free [Conly

et al., 2011]. However, considering LT hydrothermal and distal HT hydrothermal deposits, fluid chemistry for major elements is close to seawater composition. Hence this classification scheme is not well-suited for the compositional range found for oceanic Fe-Mn deposits, although it does separate marine and continental Mn-oxide deposits that are not mixed with Fe oxides.

Using trace-element mobility in hydrothermal fluids and seawater, Nicholson [1992] proposed a (Co + Ni) vs (As + Cu + Mo + Pb + V + Zn) binary diagram with distinction between hydrogenetic, diagenetic, or supergene and hydrothermal precipitation. Nodules and hydrogenetic crusts are well-discriminated on this diagram, however the unusually high Co and Ni contents of samples from Wallis and Futuna plot away from the designated hydrothermal field. A similar conclusion is reached for the classification proposed by Choi and Hariya [1992] using a Ni-Zn-Co ternary diagram. The binary discrimination diagrams of Bau *et al.* [2014] are based on Nd concentrations and fractionation of the geochemical twin Y and Ho against the Ce anomaly. These diagrams demonstrate the efficiency of REY as a discriminative feature for the various genetic types of marine Fe-Mn deposits. One of the most efficacious is the Y_{PAAS}/Ho_{PAAS} ratio, which if <1 characterizes a hydrogenetic or diagenetic process. Hydrothermal deposits exhibit a wider range of ratios, mostly >1 though a continuum towards hydrogenetic ratios is observed representing the evolution of the exchange equilibrium between seawater and scavenging Fe-Mn oxides [Bau *et al.*, 2014]. Although really robust, this criterion can not be used when considering hydrogenetic samples affected by phosphatisation due to a shift of the Y_{PAAS}/Ho_{PAAS} ratio to values as high as 1.8 [Asavin *et al.*, 2010] (Figure 4). We will therefore try to accommodate this characteristic of hydrogenetic samples within our discriminative diagrams including other common discriminative features of Fe-Mn deposits.

4.2. New genetic discrimination diagrams

The objective of a new discrimination scheme therefore lies on the incorporation of new elements allowing the discrimination of hydrothermal samples from hydrogenetic and diagenetic deposits without relying solely on the metal content.

Fe-Mn deposits have long been known for their economic potential and accordingly most studies focused on the geochemistry of Fe, Mn, Cu, Ni and Co or a specific aspect of their trace element content with too few studies publishing a complete dataset including major, minor and trace elements. The published data used in the following plots were chosen to be representative of the diversity of Fe-Mn occurrences found throughout the deep ocean. Therefore data for polymetallic nodules include mixed hydrogenous-diagenetic samples from the central and north eastern part of the Pacific Ocean ($n = 149$) [Calvert and Price, 1977; Calvert and Piper, 1984; Dymond *et al.*, 1984; Hein *et al.*, 1997; Ohta *et al.*, 1999; Wegorzewski and Kuhn, 2014], diagenetic nodules from the Peru basin ($n = 31$) [Von Stackelberg, 1997], as well as samples from the Indian Ocean ($n = 18$) [Pattan and Banakar, 1993; Balaram *et al.*, 1995; Baturin and Dubinchuck, 2010]. Data used for hydrogenetic crusts come from samples of the open Pacific Ocean ($n = 72$) [De Carlo and Mc Murtry, 1992; Bau *et al.*, 1996; Bau and Koschinsky, 2009; Asavin *et al.*, 2010], including averaged compositions for diverse areas of the Pacific ($n = 4$) [Hein *et al.*, 1997], samples from the Atlantic Ocean ($n = 31$) [Baturin and Dubinchuck, 2011; Muiños *et al.*, 2013] and the Indian Ocean ($n = 5$) [Surya Prakash *et al.*, 2012]. In addition to our own samples from Wallis and Futuna Archipelago, hydrothermal Fe-Mn samples from the literature include data from the Pacific Ocean; Mariana-Izu-Bonin Arc System ($n =$

6) [Hein *et al.*, 2008b], East Diamante Caldera (n = 6) [Hein *et al.*, 2014], Valu Fa Ridge system (n = 13) [Sun *et al.*, 2011], PACMANUS hydrothermal field (n = 18) [Zeng *et al.*, 2012], Baby bare seamount (n = 9) [Fitzgerald and Gillis, 2006], Okhotsk Sea (n = 5) [Baturin *et al.*, 2010], metalliferous sediment and silica-hematite deposits of the Blanco Fracture Zone (n = 12) [Hein *et al.*, 2008a], ironstones from Central Pacific Seamounts (n = 3) [Hein *et al.*, 1994], and bacterially mediated metalliferous sediment from Loihi Seamount, Hawaii (n = 13) [Edwards *et al.*, 2011]. Data for hydrothermal samples from the Atlantic Ocean include the ultramafic hosted deposits from the Mid Atlantic Ridge (MAR) (n = 8) [Dekov *et al.*, 2011]. Finally, data from the Eolo Seamount in the Tyrrhenian sea (n = 22) [Dekov *et al.*, 2009] and the Indian ocean (n = 3) [Surya Prakash *et al.*, 2012] are considered. Mixed type samples of hydrogenous and hydrothermal origin from the Central Indian Ridge (n = 17) [Kuhn *et al.*, 1998; Takahashi *et al.*, 2007] and the mercury- and silver-rich encrustation off the coast of California (n = 11) [Hein *et al.*, 2005] are included as well.

Major differences occur among Fe-Mn deposits when considering concentrations in high field strength elements such as Zr, Ti and the REY. Geochemical divergences for each mineral-forming process are illustrated in cross-plots (Figure 4). Using characteristics of REY fractionation such as the Ce anomaly, one of the most distinctive features encountered in the various types of Fe-Mn deposits, the Y_{PAAS}/Ho_{PAAS} ratio [Bau *et al.*, 2014], Zr or Ti content plotted against Mn/Fe ratio, and metal enrichments provide fairly good discrimination for each type of deposit. Relationships in Figures 4 and 5 reflect the control of growth rates, precipitation kinetics, and pH conditions during mineral-forming processes and overall metal concentrations and trace element budget in the source fluid. The HFSE and REY are highly depleted in hydrothermal deposits (by one order of magnitude) and richer in hydrogenetic deposits, while polymetallic nodules of mixed hydrogenetic-diagenetic origin display more limited enrichments in comparison with hydrogenetic deposits due to low contents of such elements in pore fluids. Hydrothermal deposits depletion in HFSE relates to the poor capacity of these elements to bind with the dominant chloride complex in hydrothermal fluids therefore implying a HFSE-depleted source fluid for Fe-Mn hydrothermal deposits [Douville *et al.*, 2002]. Furthermore, the fast precipitation of hydrothermal Fe-Mn deposits limits hydrogenetic enrichment of Zr, Ti and REY [Schmidt *et al.*, 2014]. In contrast, crusts and nodules growing at extremely slow rates benefit from extensive contact with seawater and pore fluids to scavenge dissolved trace metals. Of these two deposits, nodules display the largest range in composition considering Mn/Fe ratios and minor and trace element contents due to influence of both diagenetic and hydrogenetic precipitation. As exemplified in figure 4, phosphatized samples of hydrogenetic crusts [Asavin *et al.*, 2010] do not follow the discriminative features of the Y_{PAAS}/Ho_{PAAS} ratio [Bau *et al.*, 2014] and these samples could not be distinguished from non-phosphatized crusts using other criteria (Ce, REE, Zr).

The ratio of diagenetic to hydrogenetic input to nodules, and their associated minor metals, can be shown qualitatively by the Mn/Fe ratio. The higher the Mn relative to Fe, the higher is the diagenetic input. Nodules analyzed from the global ocean show that there is a continuum between the diagenetic and hydrogenetic end-members (Figure 5). Metals (Ni, Cu, Co), HFSE and REY in Fe-Mn deposits are mainly derived from seawater with hydrogenetic precipitation in Fe-Mn crusts and nodules. Further enrichment in elements such as Mn, Cu, Ni and Zn occur during diagenesis whereby metals are released to pore fluids through the dissolution of the Mn oxyhydroxide fraction of the

sediment releasing carried metals which become available to migrate up to the nodules at the oxic-suboxic interface [Ohta *et al.*, 1999; Koschinsky *et al.*, 2001]. The diagenetic process does not link to Fe, Co, REY and HFSE enrichment in polymetallic nodules as Fe is mainly re-precipitated in the sediment as Fe oxyhydroxides or associated with silica to form nontronite (Calvert and Piper, 1984). Moreover Co, REY, and HFSE limited mobility in interstitial waters compared to Cu, Ni, and Zn explains their relative enrichment in the most hydrogenetic samples and depletion with increasing diagenetic input [Jung and Lee, 1999; Ohta *et al.*, 1999; Schultz, 2006; Baturin and Dubinchuck, 2009].

Therefore, Co, HFSE and REY enrichment in Fe-Mn deposits characterize hydrogenetic precipitation and it would be tempting to associate them in a new diagram to discriminate diagenetic and hydrothermal formation. However with unusual Co concentration averaging 0.6% and up to 2.2% in hydrothermal samples from Wallis and Futuna, it is essential not to combine Co, HFSE and REY to separate metal-rich hydrothermal deposits from crusts and nodules.

4.3. Incorporating REE and HFSE in a new classification scheme

The choice of elements to incorporate in a new discrimination diagram should accommodate variations in hydrogenous or diagenetic inputs to nodules, oxic/suboxic diagenesis in nodule bulk compositions, mixed hydrothermal-hydrogenetic formation, and metal-rich Fe-Mn hydrothermal deposits. We propose to use a first apex representing combined Fe and Mn concentrations $(Fe + Mn)/4$ (wt.%), an index that represents the main constituent of Fe-Mn samples. The second apex represents the various metal enrichments produced by the three precipitation processes: $10 \cdot (Cu + Ni)$ in wt.%. Cobalt is deliberately left out of this apex as a common marker of hydrogenetic precipitation although its addition does not change fundamentally samples positioning, and could be considered in the case of extreme Co enrichment. HFSE and REY allow for the separation of hydrothermal samples from hydrogenetic and diagenetic deposits (Figure 4). The last apex should therefore be formed by a combination of these elements. As studies of Fe-Mn deposits have not always presented complete minor and trace element data, we will focus on the most commonly published HFSE (e.g. Ti and Zr) and REY. The enrichment in REY and other HFSE is a function of growth rate, fluid source and chemistry, and also represents uptake of seawater complexes by Fe and Mn oxyhydroxides/oxides. Carbonates are the main complexing agent for REE; $REE-CO_3^+$ and $REE-CO_3^{2-}$ accounting for at least 85% of REE ligands in seawater [Schijf *et al.*, 2015], while Zr or Ti are dominantly complexed with hydroxides [Bruland, 1983; Bau *et al.*, 1996] and enriched by surface complexation. Combining these elements that are fractionated by sorption on either Fe- or Mn-oxides has the objective of creating a restricted field for hydrogenetic precipitates in the diagram by including both scavenger phases and eliminates the influence of Mn/Fe ratios. Cerium constitutes probably the most efficient element amongst the REE series to use as a discriminative feature for Fe-Mn deposits. Indeed, Ce is easily hydrolyzed and continuously and irreversibly scavenged from seawater on the surface of Mn oxides [Takahashi *et al.*, 2007] and positive Ce anomalies in Fe-Mn deposits are therefore regarded as typical of hydrogenetic precipitation. Owing to the differences in precipitation kinetics among the different Fe-Mn deposits and irreversible Ce uptake from seawater,

this element will be most enriched in hydrogenetic deposits, lower in diagenetic deposits, and depleted in hydrothermal deposits.

Yttrium and La were also considered as these elements show strong enrichment in Fe-Mn deposits and are commonly analyzed in published studies. Combinations using Zr and Ce with either La or Y give similar results owing for the consistent fractionation of Y and La across the diverse environments of formation of Fe-Mn deposits. On the other hand, using an apex combining Zr, Y and La brings scatter in samples distribution. Notably, mixed-type deposit deviate from their predicted position between hydrothermal and hydrogenetic deposits. The absence of discrimination using La and Y relates to their common levels of enrichment in hydrogenetic and mixed hydrogenetic-hydrothermal deposits whereas using Ce brings more weight to the HFSE-REY apex. Indeed Ce will be strongly enriched (positive Ce anomaly) in purely hydrogenetic precipitate whereas the faster growth rate of mixed hydrogenetic-hydrothermal deposits (up to 29 mm/Ma) will prevent the formation of a positive Ce anomaly due to slow Ce oxidation kinetics [Kuhn *et al.*, 1998]. Consequently, using a combination of the most distinctive features of REE and HFSE behavior highlighted here, an apex with $100 * (Zr + Y + Ce \text{ in wt.\%})$ is a viable discriminant (Figure 6).

In the resulting ternary diagram, hydrogenetic crust samples define a well-delineated group close to the HFSE and REY apex (Figure 6A). These elements can be used as a marker for hydrogenetic input over diagenetic input, allowing discrimination of these contributions for polymetallic nodules that are otherwise ambiguous. Following the genetic classification of polymetallic nodules in Figure 5 [Dymond *et al.*, 1984], we observe a partitioning of nodule data (Figure 6B) in accord with the position of hydrogenetic crust data. The transition from hydrogenetic to diagenetic favors high concentration in Ni and Cu at the expense of HFSE and REY defining a trend from the potential economic-metal apex with diagenetic nodules towards the REY-HFSE apex with mixed hydrogenetic-diagenetic samples. Data for diagenetic suboxic samples from the Peru Basin [Von Stackelberg, 1997] lack Y concentrations. Concentrations included in the calculation of the HFSE apex therefore used the average Y concentration of 69 ppm for Peru Basin samples from Hein and Koschinsky [2013] including a standard deviation of ± 30 ppm calculated from the nodule dataset used in this study ($n = 184$). These samples define here a line moving towards the Fe-Mn apex with a consistent HFSE-REY index at the expense of the metal content. This specific nodule trend is consistent with the evolution of the bulk Ni + Cu content in polymetallic nodules described by Halbach *et al.* [1981]. Indeed, transition from hydrogenetic to oxic diagenetic nodules favors metal enrichment with high grades of Ni + Cu with Mn/Fe ratios as high as 5. However, transition to suboxic diagenetic samples from the Peru Basin [Von Stackelberg, 1997] with bulk Mn/Fe ratio up to 100 display decreasing metal contents [Halbach *et al.*, 1981; Dymond *et al.*, 1984]. Dominant suboxic conditions favor formation of a strong gradient of Mn and Fe in the pore waters by dissolution of Mn oxides and reduction of ferric iron in the sediment in the presence of required quantities of organic carbon. This abundance of Mn^{2+} and Fe^{2+} therefore compete with Cu^{2+} and Ni^{2+} for incorporation in the todorokite lattice promoting the shift observed in the ternary diagram [Halbach *et al.*, 1981; Hein and Koschinsky, 2013]. Detailed analysis of nodule microlayers from the Peru Basin [Wegorzewski and Kuhn, 2014] have shown that these trends are only valid when considering bulk composition and that otherwise nodules are made of alternating layers of hydrogenetic and diagenetic composition in various proportions. In the scope of this new discrimination diagram, only bulk compositions are considered.

In Figure 6C, the use of REY and HFSE separates the overlap of metal-rich hydrothermal samples with those of hydrogenetic or diagenetic origins as compared to other schemes. Metal-rich samples from Wallis and Futuna are spread between the Fe-Mn and Cu-Ni apex. Most hydrothermal samples fall otherwise close to the Fe-Mn apex in accordance with their typical depletion in HFSE and minor metals (Cu, Ni, Co, Zn).

4.4 - Limits of the discrimination diagram

Samples which do not fit the major trends observed for the majority of the dataset are presented in Figure 6D. Most of these samples present specific atypical characteristics or constitute mixed-type deposits and allow for the exploration of the diagram's limits as to which samples can be correctly classified using this discrimination scheme. Mixed hydrothermal-hydrogenetic crusts samples [Hein *et al.*, 2005; Muiños *et al.*, 2013] result from the incorporation of hydrothermally derived elements into hydrogenetic crusts either as fall-out particles or acquire a hydrothermal signature through the input of LT hydrothermal fluids. Hydrogenetic samples from the Indian Ocean Ridge display such characteristic with a faster growth rate supported by distal hydrothermal supply which in turn impacts the time available for HFSE and REY uptake from seawater [Kuhn *et al.*, 1998; Takahashi *et al.*, 2007]. Samples from the Southern California Borderland present Hg-Ag enrichment, Ce positive anomalies, Co and REE concentration intermediate between hydrogenetic and hydrothermal deposits which highlight a mixed hydrothermal-hydrogenetic geochemical signature [Hein *et al.*, 2005]. As observed on Figure 6D, these samples plot in an intermediate position between hydrogenetic crusts and hydrothermal deposits, supporting the use of HFSE and REY as a discriminant in this diagram.

Some hydrothermal samples from the silica-hematite deposits [Hein *et al.*, 2008a] display a nearly pure Silica composition with less than 3% Fe. These samples are scattered in the middle of the diagram due to the lack of representability of each apex considering silica dilution. Samples with Si > 70% and at least 6% Fe plot well within the hydrothermal field (Figure 6C). It is possible to consider an apex $(\text{Fe} + \text{Mn} + \text{Si})/5$ as a substitute to better accommodate specific samples with extreme Si enrichment, usually of hydrothermal origin (Supplementary Figure S1). Comparable mineralogical impact is observed for a hydrogenetic crust sample [Muiños *et al.*, 2013] where $\delta\text{-MnO}_2$ is 71% and todorokite is present, compared to 85-99% $\delta\text{-MnO}_2$ for the rest of the sample set from this area; todorokite is uncommon for open-ocean hydrogenetic crusts but common in continental margin hydrogenetic crusts [Conrad *et al.*, 2016] which might account for the unusual signature of this sample. With regard to other samples from Muiños *et al.* [2013], the important presence of non Fe-Mn phases (30% of calcite and dolomite) shift the sample position towards the Fe-Mn apex.

Some hydrothermal sediments from Eolo Seamount scatter along the Fe-Mn – HFSE-REY side of the diagram far from other hydrothermal samples. This distribution highlights a strong enrichment in HFSE that is attributed to the remobilization and redeposition of hydrothermal particle mixing with detrital material (> 65% clays in bulk sample) [Dekov *et al.*, 2009].

Another limit of this diagram lies in the distinction between metal-rich hydrothermal deposits and suboxic diagenetic nodules that cover similar fields. However, although these two deposit types might plot in a similar area on the diagram, they can be distinguished by mineralogy or by plotting the Mn/Fe ratio vs (Zr + Y + Ce). Besides, these two sample types would have been collected from quite different environments and have very different appearances.

The use of this diagram as a genetic discriminant therefore requires that samples plotted in it contain more than 5% Fe and Mn when the major phase is silica like in the case of the silica-hematite deposits. Silica dilution of the Fe-Mn fraction can be significant (up to 95%) without changing much the appropriate positioning of samples because silica is not known to be associated with more than trace amounts of metals, HFSE and REY. If non Fe-Mn oxide minerals are present, then a >70% Fe-Mn portion is necessary to correctly discriminate sample genesis; for example with >30% carbonate, clays or sulphides, samples cannot be correctly discriminated on this diagram. Titanium and Zr must be used with caution because these elements are abundant in both volcanic rocks hosting most Fe-Mn deposits and in detrital clay minerals that may be incorporated in Fe-Mn deposits. It is therefore recommended to look for potential contamination by mafic volcanic grains from the substratum by looking for high Al_2O_3 contents in bulk samples and determine, when possible, the carbonate- and clay-free fraction of metalliferous sediments to avoid the contamination by non-metalliferous material as exemplified by samples from Eolo Seamount [Dekov *et al.*, 2009].

4.5 - New discrimination diagram for Fe-Mn oceanic deposits

The data distribution in Figure 6 supports the efficacy of HFSE and REY as a discriminant for Fe-Mn oceanic deposits, as introduced by Bau *et al.* [2014]. As highlighted here, previously proposed discrimination schemes do not completely distinguish metal-rich hydrothermal samples from the two other dominant types of Fe-Mn deposits, as well as separation of mixed deposit types. In addition, phosphatized hydrogenetic crust samples are positioned within this diagram among other crusts. Consequently this new scheme provides increased sensitivity for discrimination among the genetic processes that produced these various deposit types, and thus provides a powerful tool.

Based on data distribution on this ternary diagram, we propose the following identification of genetic fields for the formation of oceanic Fe-Mn deposits (Figure 7). This figure displays the detailed relations among the three genetic processes through well-defined fields for each deposit-forming process without overlap of metal-rich hydrothermal samples and hydrogenetic samples. This scheme allows for the identification of fields possibly representative of oxic and suboxic diagenesis within nodules, the trend between hydrogenetic and diagenetic end-members that forms a continuum, and identifies mixed genetic types such as the presence of hydrothermal particles within hydrogenetic crusts. This scheme does group hydrothermal Fe oxides and Mn oxides into a single field.

4.6. Alternative classifications for driving exploration at sea

Although robust, the new discrimination scheme (this study) and the discrimination diagrams proposed by Bau *et al.* (2014) cannot be easily applied to historical data because of the lack of REE and HFSE data. Additionally, analyses of REE requires land-based analytical techniques and thus discrimination of Fe-Mn mineralization using REE cannot be done at sea, which would help direct exploration. As a consequence, we investigated alternatives to the $100*(\text{Zr}+\text{Ce}+\text{Y})$ apex using elements that are widely available in the literature (e.g. Ti, Co and Ce) and/or that can be analyzed at sea using a compact, benchtop ED-XRF spectrometer (e.g. Ti, Co, Zr and Y). The ship-board proposed apexes for ternary diagrams include: (A) $20*\text{Ti}$, (B) $50*\text{Co}$, (C) $50*\text{Ce}$, (D) $30*(\text{Co}+\text{Ce})$, (E) $50*(\text{Ti}/5 + \text{Ce})$, (F) $200*(\text{Zr}+\text{Y})$ (Supplementary Figure S2), with all elements expressed in wt.%.

A Ti apex brings a lot of uncertainty and scattering, notably for hydrothermal samples, probably due to contamination of samples by the protolith, which increases the HFSE elements. The presence of protolith within the mineralized sample is relatively common during sampling and its influence can be verified in this configuration by checking the amount of aluminum. Compared with the hydrothermal field identified in Figure 7, samples spreading towards the HFSE apex exhibit increasing Al content mostly above 2% and up to 7.7% whereas samples correctly positioned have less than 0.9% Al.

Combinations using Co works well as a discriminant for most Fe-Mn deposits but fail to accommodate Co-rich hydrothermal deposits such as samples from Wallis and Futuna. The use of only Ce as an apex also works in the absence of Zr and Y data, however it therefore represents incorporation dominantly through Mn oxides. In addition, discrimination between hydrothermal samples and diagenetic nodules cannot be made solely on the basis of this diagram owing to their similar contents of Ce. As exemplified in previous combinations, Ce constitutes the most effective discriminant among the REE and HFSE for deep-sea Fe-Mn deposits. It can therefore be used as a viable apex in absence of more complete data, although it is not adapted for on-board exploration as instrumental errors are important for Ce measurement by ED-XRF. Consequently, the scheme which uses the $200 \times (\text{Zr} + \text{Y})$ apex represents the best alternative to our preferred discrimination diagram to use at sea. In the absence of data for Ce, the zone for hydrogenetic crust is less restrictive but interestingly, Zr and Y can be easily determined at sea using compact, benchtop ED-XRF spectrometer (Figure S3; Supplementary Information). This easy-to-use discrimination diagram, aside from deciphering the nature of Fe-Mn±Si mineralization (i.e. hydrogenetic crusts, polymetallic nodules and metal-rich/metal-poor hydrothermal precipitates), would be useful for driving deep-sea exploration campaigns.

5. Conclusions

Oceanic Fe-Mn deposits have major differences in HFSE enrichments and REE signatures. Such features can be used and incorporated into a new discrimination scheme. Hydrogenetic crusts possess high HFSE concentrations with strong positive Ce anomaly, followed closely by concentrations in polymetallic nodules, whereas hydrothermal Fe-Mn precipitates show relative depletion in HFSE, with a negative Ce anomaly. The relation between deposit-forming processes and Fe, Mn, Cu, Ni, Co, HFSE and REY concentrations has also been demonstrated for each type of Fe-Mn deposit. Trace element enrichments such as Co, Zr, Ti and REY are favored by hydrogenetic precipitation, whereas diagenetic processes provide higher Mn, Cu, Ni concentrations when diagenetic remobilization occurs in the sediment column. Hydrothermal Fe-Mn deposits show strong depletion in Zr, Ti and REY due to rapid formation and strongly variable metal contents of fluids. Taking these differences into account, a ternary diagram was developed that clearly discriminates the various Fe-Mn deposit types. The ternary diagram uses Metals – HFSE – Fe-Mn that distinguishes the main deposit-forming processes and the interaction of those processes that form mixed-type diagenetic-hydrogenetic nodules and hydrogenetic-hydrothermal crusts, as well as possibly distinguishing oxic-suboxic bulk diagenetic deposits, and variable metal enrichment in hydrothermal deposits. Finally, we propose an easy-to-use version of this diagram to discriminate seafloor Fe-Mn

precipitates that can be used on-board ship for driving deep-sea exploration projects using XRF measurements.

Acknowledgement

We thank the crews of R/V l'Atalante and Nautille HOV (Ifremer, France) and all participants of the FUTUNA cruise (chief scientist: Y. Fouquet) for their assistance at sea. The authors would like to thank G. Bayon for his help on the method used for ICP measurements, A.S. Alix for the GIS data management and P. Fernagu for the preparation of polished sections, ERAMET, AREVA, TECHNIP, BRGM, and AMP for their financial support for the FUTUNA (2010) cruise. We are thankful as well for the review and helpful discussion with J.R. Hein and an anonymous reviewer.

A New Discrimination Scheme for Oceanic Ferromanganese Deposits using High Field Strength and Rare Earth Elements

P. Josso^{1,4}, E. Pelleter¹, O. Pourret², Y. Fouquet¹, J. Etoubleau¹, S. Cheron¹, C. Bollinger³

Figures

Figure 1: Wallis and Futuna map showing the position of the main hydrothermal mounds (stars) discovered during Ifremer's cruises.

Figure 2: Chondrite-normalized REE patterns of hydrothermal samples from Wallis and Futuna EEZ.

Figure 3: Ternary discrimination system of hydrothermal samples from Wallis and Futuna after Bonatti *et al.* [1972]. Note the abnormal distribution of samples away from the hydrothermal field due to unusual metal enrichments.

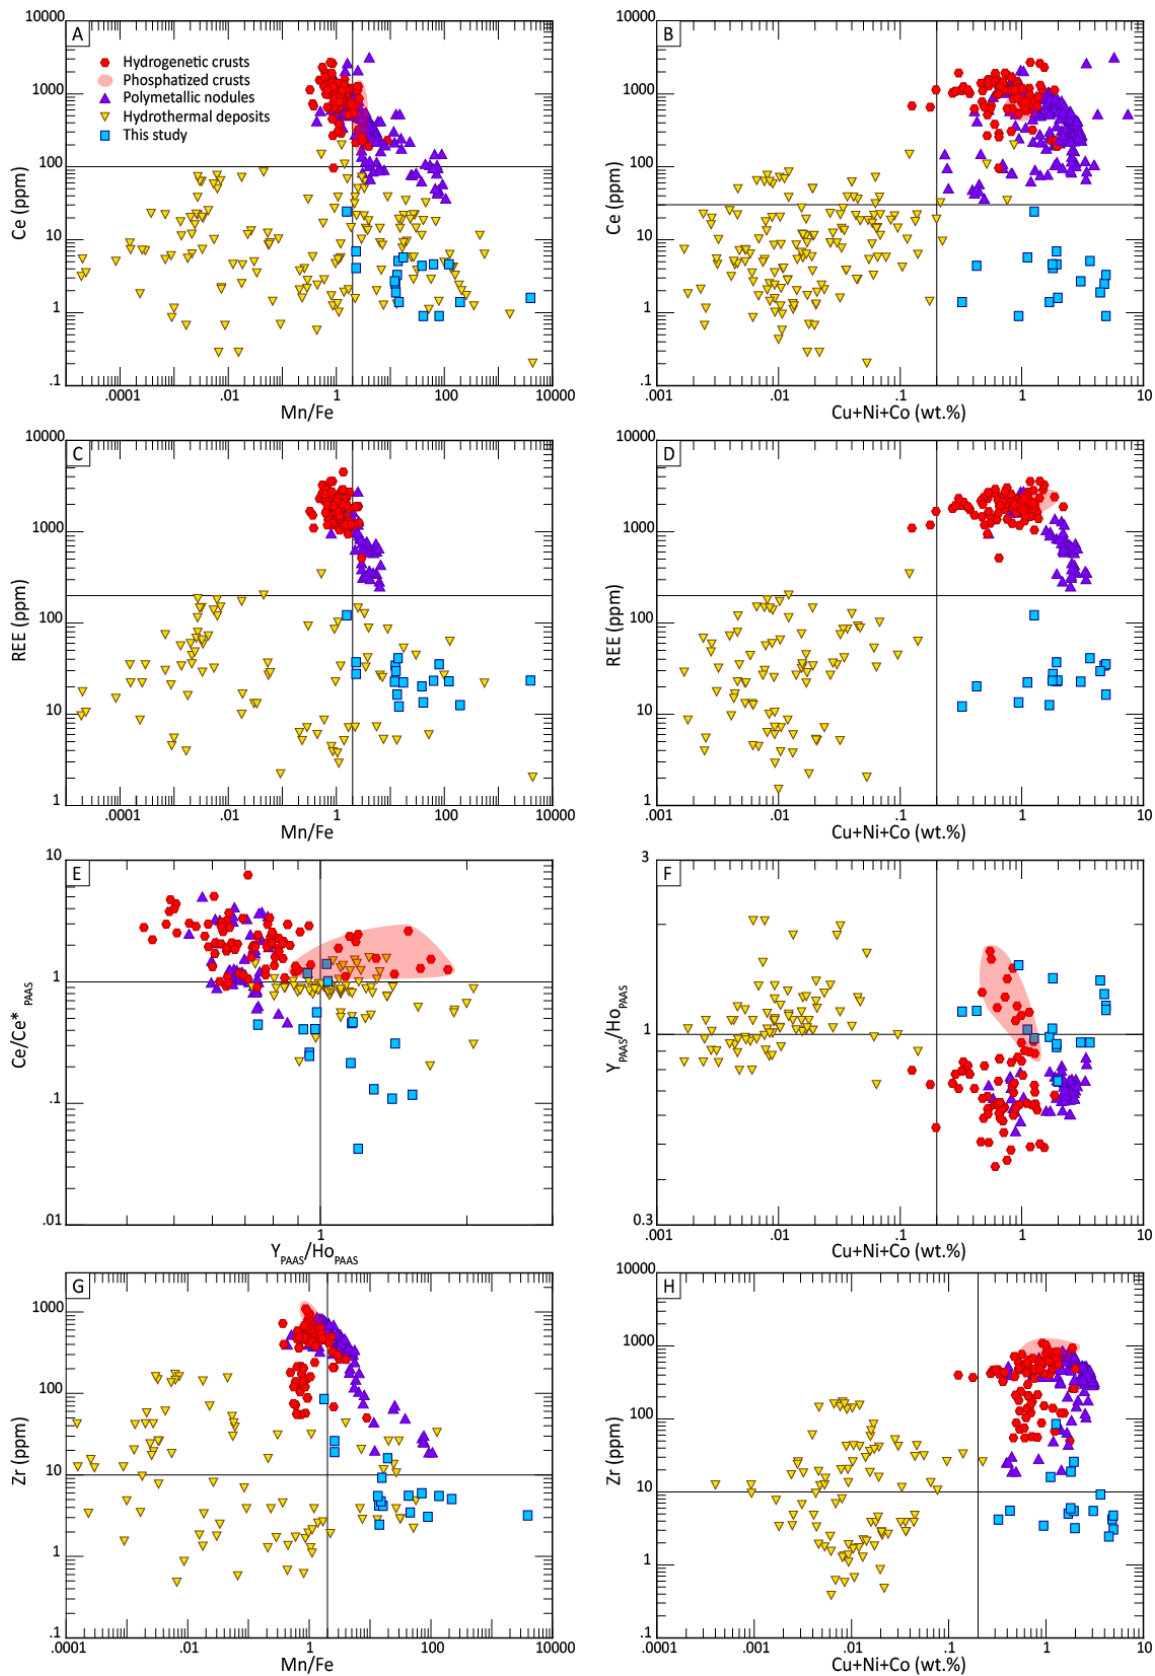

Figure 4: Discrimination diagrams displaying HFSE concentrations, Ce anomalies and $Y_{\text{PAASt}}/Ho_{\text{PAASt}}$ ratios [Bau et al., 2014] against changes in Mn/Fe ratios and potentially economic metals for oceanic Fe-Mn deposits.

Figure 5: Co/(Ni + Cu) vs Mn/Fe ratio diagram highlighting the relationship of hydrogenetic and diagenetic inputs to the composition of polymetallic nodules. Oxic and suboxic diagenetic field follow Dymond *et al.* [1984]. See text for details on data used for hydrogenetic crusts.

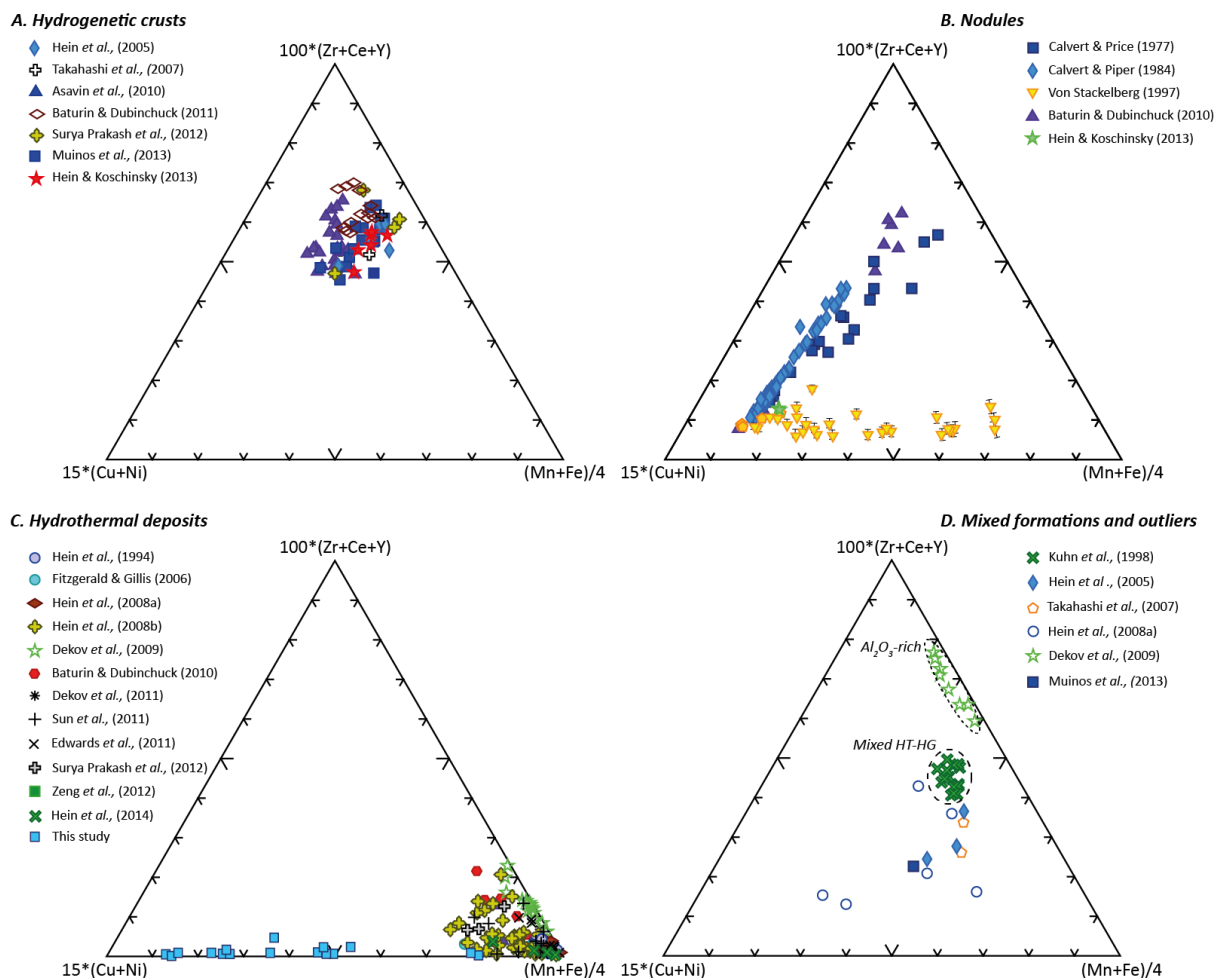

Figure 6: Alternative discriminative diagram for oceanic Fe-Mn deposits using high field strength and rare earth elements. A. hydrogenetic crusts, B. polymetallic nodules, C. hydrothermal deposits, D. mixed deposits and outliers

Figure 7: (A) Ternary discriminative diagram for genetic classification of oceanic ferromanganese deposits displaying all samples used in this study and (B) corresponding genetic fields. The dashed arrows present the mixing trends between two genetic processes highlighting the continuum between hydrogenetic-hydrothermal crusts and hydrogenetic-diagenetic nodules. Solid arrows show trends of a sample set related to only one genetic process.

Graphical abstract

Ternary diagram presenting the classification scheme and delimited areas for each genetic process involved in the formation of oceanic ferromanganese mineralizations using HFSE and REE data. The dotted arrows present the mixing trends between two genetic processes highlighting the continuum existing between hydrogenetic-hydrothermal crusts and hydrogenetic-diagenetic nodules. Solid arrows show evolution trends of a sample set related to only one genetic process without influence of another one.

A New Discrimination Scheme for Oceanic Ferromanganese Deposits using High Field Strength and Rare Earth Elements

Highlights

Discovery of metal-rich, low temperature hydrothermal deposits in South Pacific Ocean

Inability to fit in previous classification due to abnormal high metal content

Satisfying discrimination obtained combining REE and HFSE with Mn, Fe, Cu and Ni

New discrimination scheme is proposed for oceanic Fe-Mn deposits

Detailed relations highlighted between the various genetic processes
