Abstract :

Since the Industrial Revolution, the North Atlantic Ocean has been accumulating anthropogenic carbon dioxide (CO_2) and experiencing ocean acidification1, that is, an increase in the concentration of hydrogen ions (a reduction in pH) and a reduction in the concentration of carbonate ions. The latter causes the 'aragonite saturation horizon'—below which waters are undersaturated with respect to a particular calcium carbonate, aragonite—to move to shallower depths (to shoal), exposing corals to corrosive waters2,3. Here we use a database analysis to show that the present rate of supply of acidified waters to the deep Atlantic could cause the aragonite saturation horizon to shoal by 1,000–1,700 metres in the subpolar North Atlantic within the next three decades. We find that, during 1991–2016, a decrease in the concentration of carbonate ions in the Irminger Sea caused the aragonite saturation horizon to shoal by about 10–15 metres per year, and the volume of aragonite-saturated waters to reduce concomitantly. Our determination of the transport of the excess of carbonate over aragonite saturation ($xc[CO_3^{2-}]$)—an indicator of the availability of aragonite to organisms—by the Atlantic meridional overturning circulation shows that the present-day transport of carbonate ions towards the deep ocean is about 44 per cent lower than it was in preindustrial times. We infer that a doubling of atmospheric anthropogenic CO_2 levels—which could occur within three decades according to a 'business-as-usual scenario' for climate change4—could reduce the transport of $xc[CO_3^{2-}]$ by 64–79 per cent of that in preindustrial times, which could severely endanger cold-water coral habitats. The Atlantic meridional overturning circulation would also export this acidified deep water southwards, spreading corrosive waters to the world ocean.

29

Atmospheric CO_2 has increased from 280 to 400 parts per million (ppm) since the

Industrial Revolution. The global ocean has captured ~30% of this anthropogenic CO_2

(C_{ant}), acting as a climate regulator[1]. This CO_2 absorption has led to a decrease in seawater

33   pH (~0.12 units) and in the supersaturation of $CaCO_3$ (effects collectively known as ocean

34   acidification – OA). OA can particularly affect marine calcifiers[1] by favouring the

35   solubility of $CaCO_3$-based shells and skeletons[2]. Notably, deep cold-water coral (CWC)

36   reefs formed by scleractinian corals, such as the ecosystem engineer specie *Lophelia*

37   *pertusa*, are highly vulnerable to OA[3]. The global distribution of CWC seems to be partly

38   limited by the depth of the ASH, which is the boundary between aragonite-stable waters

39   above and dissolution-prone waters below[5]. In pre-industrial times, more than 95% of

40   CWC locations were found above the ASH[6], providing evidence that environments located

41   below the ASH are hostile to CWC growth. In the North Pacific (NP; Fig. 1a), where the

42   ASH is only 500 m deep[7], the distribution of aragonitic CWC is patchy and CWC do not

43   develop to large deep reef frameworks that are abundant in the North Atlantic (NA)[8] where

44   the ASH is deeper than 2000 m. OA is causing the ASH to shoal, thus exposing CWC to

45   $CaCO_3$ undersaturation. Although laboratory experiments suggest that adult *L. pertusa* can

46   acclimatize to $CaCO_3$ undersaturation[9,10], the long-term survival of CWC reefs in

47   undersaturated water is questioned because *L. pertusa* skeleton becomes weaker when

48   exposed yearlong to future OA scenarios[10], and the dead skeletal framework that supports

49   the reef itself is likely to dissolve in undersaturated waters[11].

50

51   To determine the degree of aragonite saturation of the world ocean waters, we calculated

52   $_{xc}[CO_3^{2-}]$ (in µmol kg^{-1}) by using quality-controlled global datasets of marine CO_2 system

53   measurements[12,13]. Positive (negative) $_{xc}[CO_3^{2-}]$ indicates aragonite supersaturated

54   (undersaturated) waters (see Methods). High positive $_{xc}[CO_3^{2-}]$ values occur in the NA

55   while negative values occur in the NP, which is consistent with the distribution of CWC[14]

56   below 1,000 m (Fig. 1a). About 61% (78%) of CWC found deeper than 1,000 m (1,500 m)

57   are located in the NA where $_{xc}[CO_3^{2-}] > 0$, with an average $_{xc}[CO_3^{2-}]$ of 24.5 µmol kg^{-1} (15

58   µmol kg^{-1}) that is half the natural (pre-industrial) $_{xc}[CO_3^{2-}]$ (see Extended Data Table 1).

59   The AMOC created the favourable conditions for CWC growth found in the NA by

60   conveying ventilated waters loaded with relatively high pH and positive $_{xc}[CO_3^{2-}]$ to the

61   deep Atlantic Ocean.

62

63　　In the centre of the Irminger Sea (Fig. 1b), winter deep-convection and associated deep

64　　injection of OA recorded during 1991–2016 showed a constant increase in C_{ant} from 30 to

65　　50 μmol kg^{-1} in the ventilated Subpolar Mode Water (Fig. 2a). During the same period, the

66　　atmospheric C_{ant} grew from 85 to 123 ppm. A thick layer of low salinity (< 34.91) traces

67　　the strong convection events that occurred during the first half of the 1990s and during

68　　2014–2016. During those strong convection events, Subpolar Mode Water was ventilated

69　　down to 1,500 m, showing high temporal variability and no indication of a slowing-down

70　　of deep convection[15,16]. Present-day surface ocean shows an increase of about 30% in [H$^+$]

71　　with respect to the natural (pre-industrial) value[1]. At the centre of the Irminger Sea, the

72　　[H$^+$] increase affects a layer ~1,500 m thick (Fig. 2c), the deepest signal of direct injection

73　　of OA ever observed. Since 2002, the anthropogenic perturbation caused a deepening of the

74　　isolines of 25 and 30% of anthropogenic [H$^+$] from surface to 1,500 m. The isolines of

75　　$_{xc}$[CO$_3^{2-}$] progressively ascend at about 10–15 m yr^{-1} (Fig. 2b), with some slightly faster

76　　ascension periods related to deep convection events (arrows in Fig. 2b). The effect of these

77　　deep convection events is buffered by the partial balance between the increase in the

78　　anthropogenic [H$^+$] and the decrease in the natural [H$^+$] (due to the removal of the natural

79　　CO$_2$ accumulated in old waters by remineralisation of organic matter) (Fig. 2c). Because of

80　　this biogeochemical feedback, the decrease in $_{xc}$[CO$_3^{2-}$] and the associated shoaling of the

81　　ASH are only weakly sensitive to the intensity of the deep convection.

82

83　　West of 20ºW in the subpolar NA (SPNA), the ASH observed in 2016 is 200–500 m

84　　shallower than the pre-industrial ASH (Fig. 1c). Along the 2016 Ovide section, the 25 μmol

85　　kg^{-1} isoline of the present-day $_{xc}$[CO$_3^{2-}$] runs close to the 50 μmol kg^{-1} isoline of natural

86　　$_{xc}$[CO$_3^{2-}$], indicating a 50% decrease in the availability of CO$_3^{2-}$ for deep CWC. These

87　　changes reflect the spreading of newly ventilated Subpolar Mode Water with low $_{xc}$[CO$_3^{2-}$]

88　　from the Irminger Sea to the Iceland basin.

89

90　　The 2002–2016 AMOC mean transport across the Ovide section[17] was 16.2 ± 0.8 Sv (1 Sv

91　　= 1 million m^3 s^{-1}). The upper and lower limbs of the AMOC showed contrasted $_{xc}$[CO$_3^{2-}$]

92　　(Fig. 1c) and C_{ant} (Extended Data Fig. 1), with average $_{xc}$[CO$_3^{2-}$] values of 61 ± 2 μmol kg^{-1}

93　　and 28 ± 3 μmol kg^{-1}, respectively. The upper limb of the AMOC flows northwards (above

94   the isopycnal ~1,032.15 kg m^{-3}), transporting 1,064 kmol s^{-1} of $_{xc}[CO_3^{2-}]$ (Fig. 3). About

95   40% of this transport (435 kmol s^{-1}) subducted into the lower limb of the AMOC in the

96   SPNA, while the remaining 60% was exported to the Nordic Seas[18,19]. These $_{xc}[CO_3^{2-}]$

97   transport values are between 33 and 44% lower than the transport of natural $_{xc}[CO_3^{2-}]$

98   because natural $_{xc}[CO_3^{2-}]$ values in the upper and lower limbs of the AMOC (90 ± 2 and 49

99   ± 4 µmol kg^{-1}, respectively) are much larger than the present-day values (61 ± 2 and 28 ± 3

100   µmol kg^{-1}, respectively). By vertically transporting lower $_{xc}[CO_3^{2-}]$ with respect to pre-

101   industrial, the AMOC is responsible for the decrease in pH and $_{xc}[CO_3^{2-}]$ in the deep NA.

102

103   IPCC projections[20] indicate that a warming of about 2°C will be reached when atmospheric

104   CO_2 rises to 480–520 ppm (Extended Data Fig. 2) (i.e. a CO_2 excess over pre-industrial

105   values or C_{ant} of 200–240 ppm). These figures are about two-fold the present-day

106   anthropogenic perturbation in temperature and CO_2 (1°C warming[21] and C_{ant} of 100–120

107   ppm). The $_{xc}[CO_3^{2-}]$ for a doubling of the atmospheric C_{ant} was inferred by adding 0.72

108   times present-day marine C_{ant} (Extended Data Fig. 1) to the marine $[CO_2]$ observed in

109   2002–2016 and assuming that C_{ant} changes follow the transient steady approximation[22,23]

110   (see Methods). The projected slow-down of the deep convection by the end of the century

111   should not invalidate this approach because, as concluded above, the decrease in $_{xc}[CO_3^{2-}]$

112   is only weakly sensitive to the intensity of the deep convection. When doubling the

113   atmospheric C_{ant}, the volume of aragonite-saturated deep waters in the Iceland basin and the

114   Irminger Sea decreases dramatically as shown by the 1,000–1,700 m shoaling with respect

115   to pre-industrial depths of both the ASH and the isolines of 25–50 µmol kg^{-1} of $_{xc}[CO_3^{2-}]$

116   (Fig. 1c). A most striking feature is the vanishing of the vertical gradient of $[H^+]$ caused by

117   OA (Extended Data Fig. 3), due to the relatively rapid deep injection of C_{ant} by the AMOC,

118   leading to the homogenization of the pH in the whole water column. The disappearance of

119   the vertical gradient of pH would lead to a substantial weakening of the vertical gradient of

120    $_{xc}[CO_3^{2-}]$.

121

122   We find that doubling the atmospheric C_{ant} could result in 70% of the CWC deeper than

123   1,500 m in the NA living below the ASH and being exposed to negative $_{xc}[CO_3^{2-}]$

124   (Extended Data Table 1). An average reduction of 75% in $_{xc}[CO_3^{2-}]$ with respect to pre-

125   industrial would be observed for the CWC living below 1,000 m. This may occur as soon

126   as 2050 in a business as usual scenario (SSP5, see Extended Data Fig. 2)[4]. Our data-based

127   results are in line with the IPCC projections[24] that point to OA being a serious threat for

128   deep (> 1,000 m) CWC habitats in the NA by 2100. However, most recent model studies

129   showed large discrepancies in their estimates of the extent of CWC habitats that could be

130   exposed to corrosive waters by the end of the century. The proportion of CWC projected to

131   live below the ASH varies between 23% and 70% of its present-day area for the most

132   recent simulations using business as usual concentration pathways[6,25]. The portion could

133   reach 85% of the Northeast Atlantic CWC surfaces by 2060[26]. Our findings support the

134   latter projection. We show that the water masses of the lower limb of the AMOC are

135   becoming more acidic. Those water masses are ventilating the deep layers of the world

136   ocean and propagating the acidification threat to the CWC habitats of the world ocean. We

137   estimate that for a doubling of the atmospheric C_{ant}, the average $_{xc}[CO_3^{2-}]$ below 1,000 m

138   would become negative for the world ocean (Extended Data Table 1), indicating that most

139   of the deep CWC habitats of the world ocean may be exposed to corrosive waters by 2050.

140

141   Models predict a slow-down of 25% of the mid-latitude AMOC by the end of the present

142   century[20], which would lead directly to decreasing volume of the southward export of

143   waters with negative $_{xc}[CO_3^{2-}]$ to the global deep ocean. However, the AMOC reduction

144   would also lead to a reduction of the ventilation of the deep ocean at mid-latitudes and,

145   therefore, to a reduction of the dissolved oxygen and pH through remineralisation

146   processes[27–29]. Therefore, future AMOC slow-down could contribute to worsen the

147   acidification threats for deep CWC.

228

229 **Aragonite saturation and carbonate ion excess**

230 Aragonite is one of the $CaCO_3$ metastable forms used by calcifying marine organisms to

231 build their shells[30,31]. A measure of the bioavailability of aragonite is the *in situ* degree of

232 aragonite saturation (Ω_A) given by Eq. (1):

233
$$\Omega_A = \frac{[ca^{2+}][co_3^{2-}]_{is}}{K_A} \qquad (1)$$

234 where $[Ca^{2+}]$ is the concentration of the major ion calcium, $[CO_3^{2-}]$ is the concentration of

235 the carbonate ion, and K_A is the $CaCO_3$ aragonite solubility product. Subscript "is" denotes

236 at *in situ* temperature and pressure conditions. $[Ca^{2+}]$ is conservative and is obtained from

237 salinity (S) through Eq. (2)[32]:

238
$$[Ca^{2+}] = 0.01028 \times S/35 \qquad (2)$$

239 Another convenient measure of the aragonite saturation is the difference between $[CO_3^{2-}]_{is}$

240 and the $[CO_3^{2-}]$ at saturation ($[CO_3^{2-}]_{sat(\Omega A = 1)}$), which is the excess of carbonate ion

241 concentration over aragonite saturation ($_{xc}[CO_3^{2-}]$):

242
$$_{xc}[CO_3^{2-}] = [CO_3^{2-}]_{is} - [CO_3^{2-}]_{sat(\Omega A=1)} \; (3).$$

243 Positive (negative) $_{xc}[CO_3^{2-}]$ indicates that water is supersaturated (undersaturated) with

244 respect to aragonite. The $_{xc}[CO_3^{2-}]$ is an absolute measure of the tendency for the aragonite

245 mineral to precipitate/dissolve[33] so that, contrary to the widely used Ω_A that is a ratio, it is

246 founded to compute $_{xc}[CO_3^{2-}]$ transport. In addition, changes in $_{xc}[CO_3^{2-}]$ are directly

247   comparable with changes in $[CO_3^{2-}]_{is}$, which in this study was computed from total

248   alkalinity (A_T) and total dissolved inorganic carbon (C_T). The acid dissociation constants of

249   Dickson and Millero[34] and aragonite solubilities of Mucci[35] were selected to determine

250     $_{xc}[CO_3^{2-}]$ and other derived variables of the marine CO_2 system using the CO2SYS

251   toolbox[36,37].

252

253   **Present, natural and projected values of $_{xc}[CO_3^{2-}]$ and $[H^+]$**

254   Present $_{xc}[CO_3^{2-}]$ and $[H^+]$ were determined using measured data of the marine CO_2 system

255   (A_T , C_T and pH), temperature, salinity and pressure. We separated anthropogenic from

256   natural $_{xc}[CO_3^{2-}]$ and $[H^+]$ by assuming that the natural component corresponds to an ocean

257   in equilibrium with a pre-industrial atmosphere, whereas the remaining is anthropogenic.

258   Along the Ovide section, we determined the anthropogenic CO_2 (C_{ant}) using the back-

259   calculation φC_T^o method[19,38,39] with an overall uncertainty of ±5.2 μmol kg^{-1}. For the

260   Nordic Sills, the parameters of the marine CO_2 system were taken from Jeansson et al.[18].

261   Natural C_T was determined by subtracting the C_{ant} to the measured C_T. Natural $_{xc}[CO_3^{2-}]$

262   and $[H^+]$ were determined using measured A_T and natural C_T and the equations of the

263   marine CO_2 system using CO2SYS toolbox[36,37].

264   The Shared Socio-Economic Pathways, SSP[4] (Extended Data Fig. 2), indicate that the

265   doubling of the present atmospheric C_{ant} of 100–120 ppm, i.e. atmospheric CO_2 of 480–520

266   ppm (200–240 ppm over pre-industrial values), would lead to a 2ºC-warming scenario. The

267     $_{xc}[CO_3^{2-}]$ and $[H^+]$ for this scenario were calculated by doubling the present atmospheric

268     $C_{ant.}$ The comparison of the observed changes in C_T and chlorofluorocarbons with those

269   predicted from an eddy-permitting ocean circulation model confirmed that C_{ant} changes

270   follow the transient steady state (TSS) approximation[22,23,40]. This means that C_{ant} increases

271   over time through the whole water column proportionally to the increase in C_{ant} in the

272   surface mixed layer. Hence, we estimated the seawater C_{ant} for the doubling of atmospheric

273   C_{ant} from the present-day seawater C_{ant} considering that the change in the seawater surface

274   C_{ant} follows the change in atmospheric CO_2. The seawater C_{ant} for this scenario was

275   estimated to be $72 \pm 3\%$ higher than the present seawater C_{ant} (Extended Data Fig. 4), based

276   on a large range of temperatures (0–20ºC) and a CO_2 air-sea disequilibrium[41] of $10 \pm 5\%$.

277   The $_{xc}[CO_3^{2-}]$ and $[H^+]$ for the doubling of atmospheric C_{ant} scenario were determined by

278   adding the 0.72 times the present seawater C_{ant} to the measured C_T and using measured A_T

279   and temperature. [H^+] is given in pmol kg^{-1} as the log^{-1} of pH$_T$ (in total scale). The

280   uncertainty range for the ASH for the doubling of atmospheric C_{ant} scenario (milky area in

281   Fig. 1c) was determined considering an atmospheric CO_2 concentration of 480–520 ppm.

282

Present, natural and projected carbonate ion excess at cold-water coral (CWC)

locations

285   The stony coral database was derived from records compiled by Rogers et al.[42], Hall-

286   Spencer et al.[43] and a database of *L. pertusa* records compiled by the United Nations

287   Environment Programme – World Conservation Monitoring Centre (UNEP-WCMC) based

288   in the CWC Global distribution[44]. From the obtained 6,553 CWC records, we removed

289   those without geo-referenced coordinates or depth data, those shallower than 1,000 m, and

290   those characterized as dead or fossil, obtaining 548 CWC records (Fig. 1a and Extended

291   Data Table 1). To determine the physicochemical characteristics of the seawater

292   surrounding those 548 CWC locations, we used a multiparametric interpolation method

293   (Water Mass Properties [WMP] interpolation method)[45] to interpolate *in situ* temperature,

294   salinity, A_T and C_T from the quality controlled GLODAPv2 database[12,13]. The WMP

295   method improves the estimates obtained from purely spatial interpolation by applying a

296   weighting process using the distances in conservative parameters and using a helper

297   database with higher resolution (World Ocean Atlas[46–49]) for these conservative parameters.

298   The C_{ant} at those 548 CWC locations for 2010 was interpolated from the C_{ant} given by

299   Khatiwala et al.[50]. Following the same procedure as that described above, the present,

300   natural and projected $_{xc}[CO_3^{2-}]$ for a doubling of atmospheric C_{ant} were determined. The

301   results are summarized in Extended Data Table 1.

302

Circulation of carbonate ions and anthropogenic CO_2 in the Subpolar North Atlantic

304   The absolute geostrophic velocity fields orthogonal to the Ovide sections were determined

305   using an inverse model constrained by subsurface acoustic Doppler current profiler

306   measurements and an overall mass conservation constraint[17,51–53]. The resulting absolute

307   velocity fields are consistent with independent altimetry measurements[52] and estimates of

308   the western boundary current transport[53] at the time of the Ovide cruises. The velocity

309   fields are representative of the month of the cruise and the seasonal variability was removed

310   as explained in Pérez et al.[19]. The mean velocity field of the Ovide section during 2002–

311   2016 is shown in Extended Data Fig. 5. Transports of $_{xc}[CO_3^{2-}]$, $[H^+]$, C_{ant} and $[CO_3^{2-}]$ were

312   calculated using the velocity field, density and the tracer concentration ($_{xc}[CO_3^{2-}]$, $[H^+]$, C_{ant}

313   or $[CO_3^{2-}]$) through Eq. (4):

314    $$\text{Transport}_{Tracer} = \Sigma\,[\text{Tracer}] * \text{density}_{is} * \text{velocity} * \text{area} \qquad (4)$$

315   The transports of seawater, $_{xc}[CO_3^{2-}]$, $[H^+]$, C_{ant} and $[CO_3^{2-}]$ are summarize in Extended

316   Data Table 2, Fig. 3 and Extended Data Fig. 6. The transports of $_{xc}[CO_3^{2-}]$ and $[H^+]$ are also

317   given for present, pre-industrial (natural) and doubling of atmospheric C_{ant} scenario.

318   Uncertainties in the AMOC, and in the transport of $_{xc}[CO_3^{2-}]$ and $[H^+]$ trough the Ovide

319   section were calculated as the standard error of the mean of the eight occupations of the

320   Ovide section during 2002–2016 (s.e. = std/$\sqrt{8}$). Transport at the sills was derived from

321   Jeansson et al.[18] and Pérez et al.[19] and results are summarized in Extended Data Table 3.

Figure 1 | Aragonite saturation and cold-water coral distribution. (a) $_{xc}[CO_3^{2-}]$ at 1,500 m (lower-right colorbar). Circles, diamonds and squares represent CWC locations where $_{xc}[CO_3^{2-}]<0$, $0<_{xc}[CO_3^{2-}]<25$, and $_{xc}[CO_3^{2-}]>25$ µmol kg^{-1}, respectively. Depths are gray-coded (upper-right colorbar). (b) Central Irminger Station (red star), Ovide section (dotted line) and circulation of upper (red) and lower (blue) AMOC limbs. (c) $_{xc}[CO_3^{2-}]$ observed (colour and black lines), natural (yellow-dashed lines), and for a doubling of present atmospheric C_{ant} (dashed-white line) along the Ovide section. The milky area is uncertainty for aragonite saturation horizon ($_{xc}[CO_3^{2-}]=0$). The red line separates the upper and lower AMOC limbs. Dots represent samples.
Figure 2 | Ocean Acidification at the Central Irminger Station. (a) Time evolution from 1991 to 2016 of anthropogenic CO_2 (C_{ant}, colorbar), the isohaline of 34.91 (continuous black lines) and salinity minimum (dotted black line). (b) Time evolution from 1991 to 2016 of aragonite saturation (Ω_A, contours) and excess of carbonate ion concentration over aragonite saturation ($_{xc}[CO_3^{2-}]$, colorbar). Arrows indicate the effects of deep convection events. (c) Time evolution from 1991 to 2016 of natural (pre-industrial) hydrogenion concentration ($[H^+]_{nat}$, colorbar, in pmol kg^{-1}) and percentage of change in $[H^+]$ due to anthropogenic emissions ($\% [H^+]_{ant}$, contours).
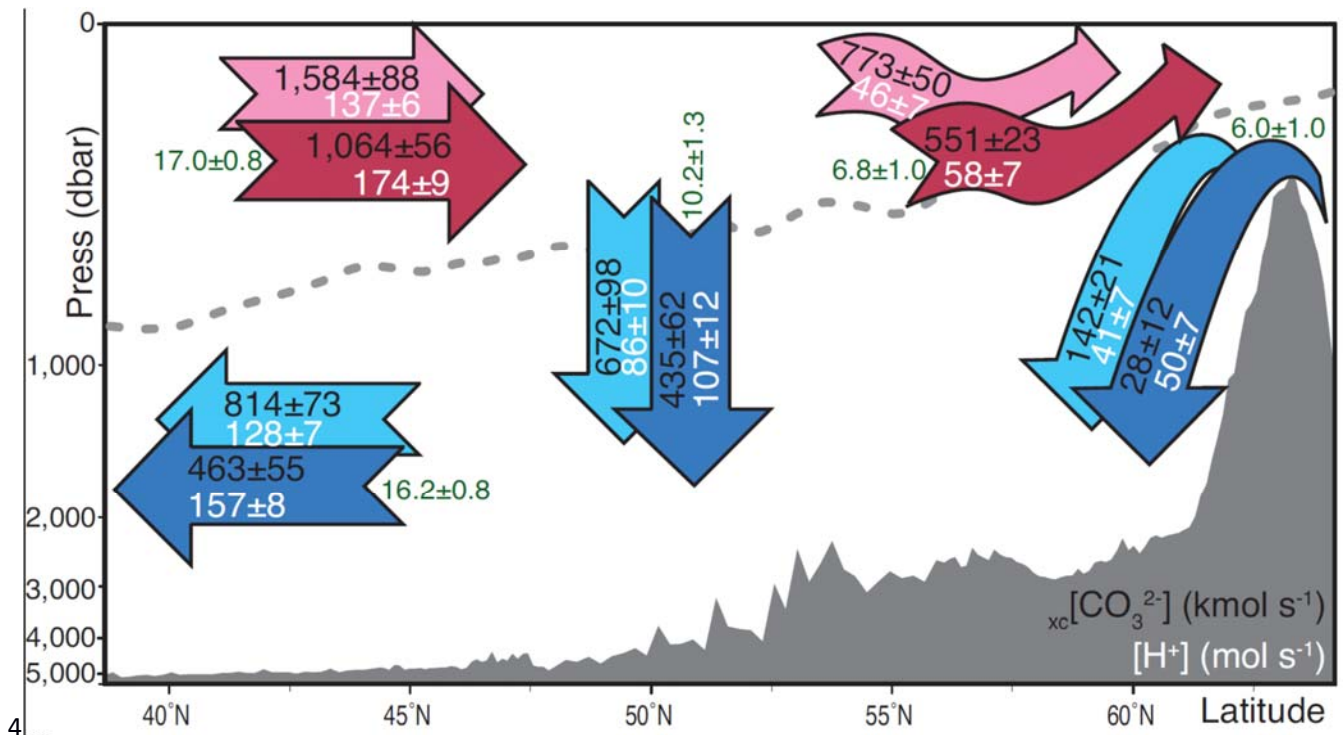

Figure 3 | Circulation of the excess of [CO$_3^{2-}$] over aragonite saturation and [H$^+$] in the Subpolar North Atlantic. Mean transports for 2002–2016 between the Ovide section and the Nordic Sills of seawater (green values, in Sv), and natural (pre-industrial; light coloured arrows) and observed (dark coloured arrows) excess of [CO$_3^{2-}$] over aragonite saturation (xc[CO$_3^{2-}$], in kmol s^{-1}, black values) and hydrogenions ([H$^+$], in mol s^{-1}, white values). Uncertainties are the errors in the mean transports across the eight occupations of the Ovide line (std/√8). The grey dotted line represents the limit between the upper and lower limbs of the AMOC.

433

434 **Extended Data Table 2 | Transports of seawater, $_{xc}[CO_3^{2-}]$, $[H^+]$, C_{ant} and $[CO_3^{2-}]$.**

435 Transport of volume (in Sv; $1\ Sv = 10^6\ m^3\ s^{-1}$), anthropogenic CO_2 (C_{ant}, in $kmol\ s^{-1}$),

436 carbonate ion concentration ($[CO_3^{2-}]$, in $kmol\ s^{-1}$), excess of carbonate ion concentration

437 over aragonite saturation ($_{xc}[CO_3^{2-}]$, in $kmol\ s^{-1}$), and hydrogen ion concentration ($[H^+]$, in

438 $pmol\ s^{-1}$) across the Ovide section during 2002–2016 in the upper and lower limbs of the

439 Atlantic Meridional Overturning Circulation (AMOC). Values of the natural (pre-

440 industrial) component (subscript 'nat') and for the doubling of atmospheric C_{ant} scenario

441 (subscript '2x') are also shown. Uncertainties (*Err_x*) are estimated as the error of the mean

442 of the eight occupations of the Ovide section (std/$\sqrt{8}$). Positive (negative) transports

443 indicate northward (southward) transport. The velocity-weighted averaged values of

444 $_{xc}[CO_3^{2-}]$ for pre-industrial, present (2002–2016) and for the doubling of atmospheric C_{ant}

445 scenario are also given.

Extended Data Figure 1 | Anthropogenic CO₂ along the 2016 Ovide section. Vertical distribution of anthropogenic CO_2 (in µmol kg^{-1}) along the Ovide section (Fig. 1b) in 2016. The black line is the isopycnal delimiting the upper and lower limbs of the AMOC.
**Extended Data Figure 2 | Projections of atmospheric CO_2 and temperature change of the five Shared Socioeconomic Pathways (SPP)[24].** Present: 1ºC warming with atmospheric CO_2 concentration ($[CO_2^{atm}]$) of 400 ppm[21], which represents an atmospheric CO_2 excess ($_{xc}[CO_2^{atm}]$) of 120 ppm ($_{xc}[CO_2^{atm}] = [CO_2^{atm}] – 280$ ppm; where 280 ppm is the pre-industrial $[CO_2^{atm}]$). The doubling of atmospheric C_{ant} scenario, i.e. 2 x present-day $_{xc}[CO_2^{atm}]$ (480–520 ppm), is within the projection range for a 2ºC-warming scenario, which could be reached in 2040–2052 according to SSP5 (pink shadowed area). SSP5 is the only scenario that results in a radiative forcing as high as the former RCP8.5 (Representative Concentration Pathways)[54].

481
Extended Data Figure 3 | Evolution of ocean acidification from pre-industrial to the doubling of atmospheric C_{ant} scenario. Hydrogen ion concentrations ($[H^+]$, in pmol kg^{-1}) along the Ovide section (Fig. 1b) for the (a) pre-industrial, (b) present (2016) and (c) doubling of atmospheric C_{ant} scenario. The black line is the isopycnal delimiting the upper and lower limbs of the AMOC.

487

Extended Data Figure 4 | Progression of anthropogenic CO₂ in surface waters versus excess of atmospheric xCO₂ at different temperatures and CO₂ disequilibriums.
Concentration of anthropogenic CO_2 ($[C_{ant}]$, light blue dots, in µmol kg^{-1}), Cant_ratio (navy dots) and Hant_ratio (red dots) versus the excess of atmospheric xCO₂ due to anthropogenic signal during 1959–2016 for (a) 2ºC and 5% of CO₂ disiquilibrium, (b) 2ºC and 15% of CO₂ disiquilibrium, (c) 20ºC and 5% of CO₂ disiquilibrium, and (d) 20ºC and 15% of CO₂ disiquilibrium. The Cant_ratio (Hant_ratio) is the ratio between the $[C_{ant}]$ ($[H^+]_{ant}$) at any time and the average $[C_{ant}]$ ($[H^+]_{ant}$) for the Ovide period (2002–2016). The computed values for the doubling of atmospheric C_{ant} scenario (excess of atmospheric xCO₂ of 220 ± 20 ppm) are also shown. The progression of the Hant_ratio fits to a straigh line, while, the Cant_ratio decreases when increasing the atmospheric xCO₂ due to the buffer capacity of the marine CO₂ system (Revelle factor). An increase of 72 ± 3% in C_{ant} above the average $[C_{ant}]$ for the Ovide period (2002–2016) is computed for the doubling of atmospheric C_{ant} scenario. This is practicaly independent of the seawater temperature and the degree of CO₂ disiquilibrium[41].

503
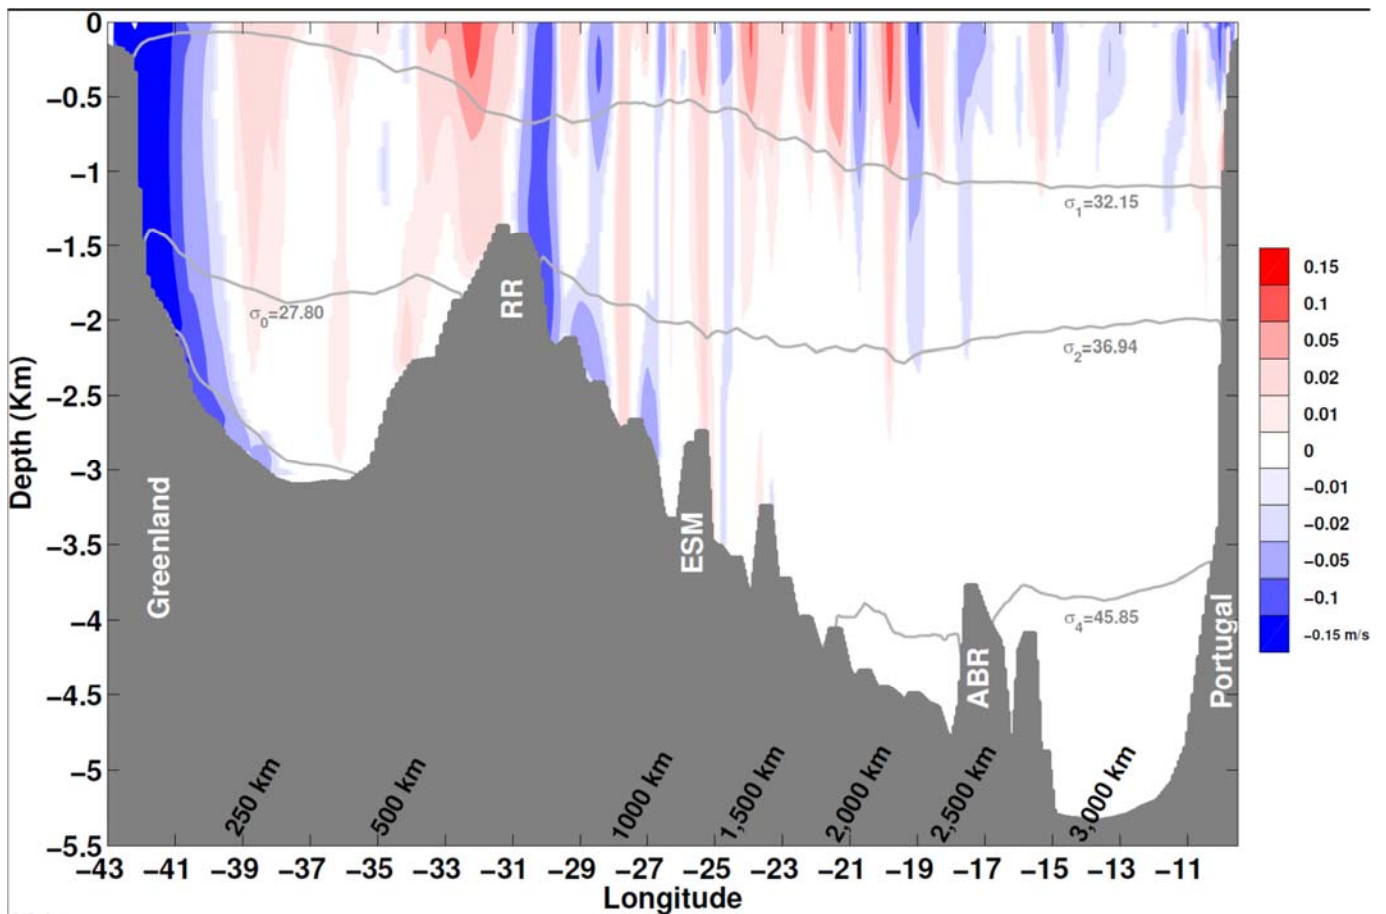

505 **Extended Data Figure 5 | Mean velocities orthogonal to Ovide.** Mean velocities (in m s⁻

506 ¹) orthogonal to the Ovide section for the period 2002–2016. The Ekman velocities,

507 estimated from winds stress averaged over the months of the cruises and equally distributed

508 over the first 30 m, were added to the geostrophic velocities derived from a box inverse

509 model[17,51–53]. Positive (negative) velocities indicate northeastward (southwestward)

510 currents. The horizontal grey lines are the isopycnals $\sigma_1 = 32.15$ kg m⁻³, $\sigma_2 = 36.94$ kg m⁻³

511 and $\sigma_4 = 45.85$ kg m⁻³. The km at the bottom of the figure indicates distance from

512 Greenland. The acronyms indicate topographic features: Reykjanes Ridge (RR), Eriador

513 Seamount (ESM) and Azores-Biscay Ridge (ABR).

514
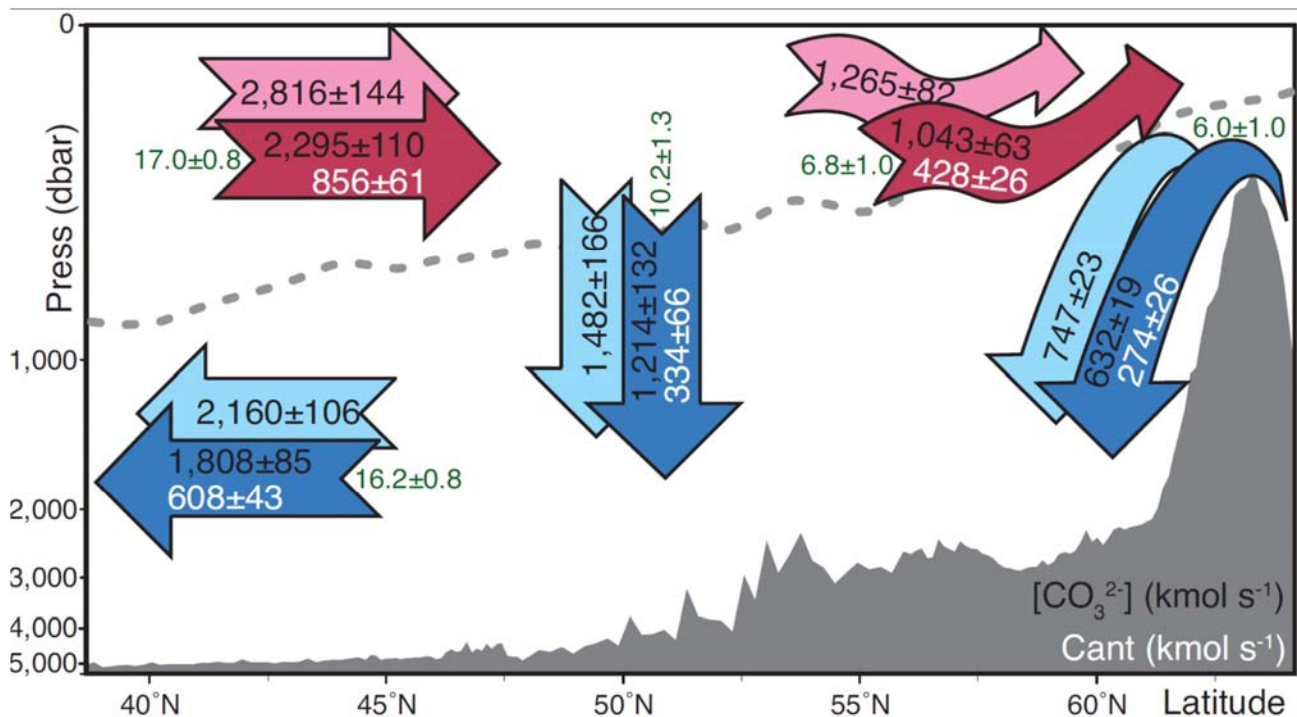

Extended Data Figure 6 | Circulation of carbonate ions and anthropogenic CO_2 in the Subpolar North Atlantic. Mean transports for 2002–2016 between the Ovide section and the Nordic Sills of seawater (green values, in Sv), and natural (pre-industrial; light coloured arrows) and observed (dark coloured arrows) carbonate ion concentration ($[CO_3^{2-}]$, in kmol s^{-1}, black values) and anthropogenic CO_2 (C_{ant}, in kmol s^{-1}, white values). Uncertainties are the errors of the mean transports across the eight occupations of the Ovide section (std/$\sqrt{8}$). Transports at the Nordic Sills derived from Jeansson et al.[18] and Pérez et al.[19]. The grey dotted line represents the limit between the upper and lower limbs of the AMOC.
