Abstract:

Growth of the black-lip pearl oyster, *Pinctada margaritifera* var. *cumingi*, was studied for an annual cycle, from March 1997 to April 1998, in the lagoon of Takapoto atoll (Tuamotu archipelago, French Polynesia). Growth in shell and in tissue were measured every 15 days on three successive age groups of cultivated pearl oysters. At the same time, hydrobiological parameters (temperature, salinity, oxygen concentration, suspended particulate matter), known to have influence on bivalve growth, were followed each week during culture. No seasonal trend was observed in hydrobiological parameters, except for temperature which varied between 26°C and 31°C. The potential food for pearl oysters (particulate organic matter, POM, mg l⁻¹) was slightly concentrated, but always available, so that, in this lagoon environment, no period seemed to be unfavourable to pearl oyster growth. Effectively, growth in shell was regular and shell did not exhibit any annual ring. Nevertheless, as it is often the case for bivalves, shell growth showed a progressive decrease with the age of pearl oyster and followed a classical Von Bertalanffy model: $H=160.5 (1-e^{-0.038 (t-3.73)})$ with H the shell height (in mm) and t the age (in months). On the other side, growth in tissue did not follow the same pattern than for shell: *P. margaritifera* exhibited reduced growth rate in tissue during the warm season (November–April) so that a seasonal growth model was more appropriate: $W_{\text{tissue}}=6.9/(1+e^{(5.58-0.208 t-0.435 \sin (2\pi/12 (t-1.427))})$ with W_{tissue} , the dry tissue weight (in g) and t the age (in months). Several results concerning growth rates should be of interest for pearl farming. Firstly, the progressive decrease measured in shell growth rate implies, for pearl seeding operations, that the sooner the nucleus is implanted, the greater is the rate of nacreous deposition on this nucleus, and shorter is the time to obtain a marketable pearl for farmers. Secondly, exhaustive comparison, between growth rates obtained in our study and those obtained in other lagoons, tended to demonstrate that there is a small but significant variability in growth between lagoons of the Tuamotu archipelago. Further investigations need to be engaged in order to determine the most suitable sites for pearl farming in French Polynesia. Finally, comparison between growth of *P. margaritifera* var. *cumingi* and growth of other pearl oysters showed that *P. maxima* but also *P. margaritifera* var. *erythraensis* would also exhibit fast growth in Polynesian waters and then, would constitute potential candidates for further Polynesian diversification projects.

Abstract

Growth of the black-lip pearl oysters, *Pinctada margaritifera* var. *cumingi*, was studied for an annual cycle, from March 1997 to April 1998, in the lagoon of Takapoto atoll (Tuamotu archipelago - French Polynesia). Growth in shell and in tissue were measured every 15 days on 3 successive age groups of cultivated pearl oysters. In the same time, hydrobiological parameters (temperature, salinity, oxygen concentration, suspended particulate matter), known to have influence on bivalve growth, were followed every weeks around system culture.

No seasonal trend was observed in hydrobiological parameters, except for temperature which varied between 26 °C and 31 °C. The potential food for pearl oysters (Particulate organic matter, POM, mg l⁻¹) was slightly concentrated, but always available, so that, in this lagoon environment, no period seemed to be unfavourable to pearl oyster growth. Effectively, growth in shell was regular and shell did not exhibit any annual ring. Nevertheless, as it is often the case for bivalves, shell growth showed a progressive decrease with the age of pearl oyster and followed a classical Von Bertalanffy model : $H = 160.5 (1 - e^{-0.038 (t-3.73)})$ with H the shell height (in mm) and t the age (in months). On the other side, growth in tissue did not follow the same pattern than for shell : *P. margaritifera* exhibited reduced growth rate in tissue during the warm season (November-April) so that a seasonal growth model was more appropriate : $W_{\text{tissue}} = 6.9 / (1 + e^{(5.58 - 0.208 t - 0.435 \sin(2\pi/12 (t-1.427))})$ with W_{tissue} , the dry tissue weight (in g) and t the age (in months).

Several results concerning growth rates were of interest for pearl farming. Firstly, the progressive decrease measured in shell growth rate implies, for pearl seeding operations, that the sooner the nucleus is implanted, the greater is the rate of nacreous deposition on this nucleus, and shorter is the time to obtain a marketable pearl for farmers. Secondly, exhaustive comparison, between growth rates obtained in our study and those obtained in other lagoons, tended to demonstrate that there is a small but significant variability in growth between lagoons of the Tuamotu archipelago. Further investigations need to be engaged in order to determine the most suitable sites for pearl farming in French Polynesia. Finally, comparison between growth of *P. margaritifera* var. *cumingi* and growth of other pearl oysters showed that *P. maxima* but also *P. margaritifera* var. *erythraensis* would also exhibit fast growth in Polynesian waters and then, would constitute potential candidates for further Polynesian diversification projects.

Key Words : *Pinctada margaritifera* - Growth - Tropical lagoon - Length-weight relationship - Biochemical composition - Matter in suspension - Pearl Culture.

1. INTRODUCTION

The black-lip pearl oyster, *Pinctada margaritifera* (Linnaeus, 1758) var. *cumingi* (Reeve), occurs throughout in the Indo-Pacific region but is abundant in the atoll lagoons of the French Polynesia where it is cultivated for its lucrative black pearls. The culture technique, which showed great variations during the last 20 years, is now stable (subsurface long-line systems) and as follows : spat settles onto artificial materials placed into the lagoon (spat collectors) and are left on the collectors for up to six months. Then, they are transferred on various ongrowing systems (lantern nets or downlines). Pearl-seeding operations begin at about 2 years of age, and pearl is produced approx. 18 months after implantation. After pearl collecting, oysters are sometimes re-implanted to produce a second pearl.

Up to now, density of cultivated pearl oysters has increased dramatically in several atoll lagoon. An important research program (PGRN) is underway to determine the carrying capacity (see review from Héral et al., 1989; Grant et al., 1993; Kashiwai, 1995) of atoll lagoons. In order to reach this aim, a first step is to build a physiological model which explains growth of pearl oyster according to its environment. These kinds of models have already been achieved for other species (Ross and Nisbet, 1990; Bacher et al., 1991; Schneider, 1992; Willows, 1992; Raillard et al., 1993; Van Haren and Kooijman, 1993; Barillé et al., 1997) but nothing is available for *P. margaritifera* in its lagoon environment. In order to build an *in situ* physiological model of growth, the entire feeding process rates have to be studied on *P. margaritifera*, preferentially on field experiments (see Robert et al., 1998; Pouvreau et al., 1999a, 1999b). Once the model is built, growth data are required to test the adequacy and reliability of the model.

Moreover, studying growth is of interest for pearl farming, since (1) flesh growth rates constitute useful indicators for pearl oyster health and suitability of the environment as they represent the integrated response of the entire physiological activity of the organisms ; and (2) shell growth rates would give precious information on pearl growth since shell increment and deposition of nacreous matter on the implanted nucleus are strongly correlated (Coeroli and Mizuno, 1985).

Growth rates in bivalve can be estimated by several combined methods : (1) analysis of size-classes in the population; (2) observation of growth rings; (3) measurement of marked individuals; and (4) successive sampling in several known and aged cohorts. Using at less one of these methods, growth rates have been measured in numerous populations of marine bivalves in temperate areas (e.g. Mason, 1957; Mann, 1979; Bayne and Worall, 1980; Richardson et al., 1982; Rodhouse et al., 1984; Thompson, 1984; MacDonald and

Thompson, 1985; Hilbish, 1986), but growth data are less frequent for tropical or sub-tropical areas (Chellam, 1978; Velez and Epifanio, 1981; Del Rio-Portilla et al., 1992; Numaguchi, 1994; Saucedo and Monteforte, 1997; Taylor et al., 1998).

More precisely, concerning *P. margaritifera*, growth rates are poorly documented. Some measurements on *P. margaritifera* var. *erythraensis* had been realised in the past, respectively in the Red Sea (Elnaeim, 1984; Nasr, 1984) and in India (Chellam, 1978, 1988) and, concerning *P. margaritifera* var. *cumingi*, some data are available for the Cook Islands (Sims, 1993, 1994) and for Polynesian waters (Coeroli et al., 1984; Buestel et al., 1995; Leduc, 1997). But, generally speaking, these studies deal only with growth in shell or concern only a single age group. Furthermore, in these works, data concerning hydrobiology are rarely supplied simultaneously.

To complete this lack of knowledge, our present work estimates *in situ* growth in shell and in flesh of 3 age-groups of pearl oysters cultivated in the lagoon of Takapoto Atoll (Tuamotu Island - French Polynesia) in relation to hydrobiological conditions and over a year period (1997-1998). This work gives also the first empirical growth models for *P. margaritifera* in French Polynesia. Reproduction of *P. margaritifera* is not described in the present work, but constitutes the subject of a further publication.

2. MATERIALS AND METHODS

2.1. Study site and environmental parameters

Growth of cultivated pearl oysters was studied in Takapoto lagoon. Takapoto atoll is located in the Tuamotu Island of French Polynesia. This atoll (Latitude 14°30' S and longitude 145°20' W) is 18.7 km long and 4.4 km wide, and presents an area of 81.7 km². Mean depth of the lagoon is 23 m, with a maximum at 55 m. Volume of waters is estimated between 1.3 km³ (Sournia and Ricard, 1976) and 2.3 km³ (Yann Morel, pers. comm.). Exchanges with the ocean are very restricted because of the absence of channel into the coral ring. Homogeneity in the body water is ensured by regular trade winds. Sometimes, calm conditions may occur, especially during warm season (November to April), causing occasional development of stratification.

Total Particulate Matter >1 µm (TPM, mg l⁻¹) are rather low (Buestel and Pouvreau, 2000), especially its organic part (POM, mg l⁻¹) which constitutes the potential food for pearl oyster. These authors showed that if spatial variations of these parameters are not important in the lagoon, temporal variations are predominant. In order to estimate accurately the range and the source of its variations, TPM was followed every week during one year, from March 1997 to April 1998, at station 1 (Fig. 1) where experimental long-lines were installed. Characteristics of weather (especially air temperature and wind in velocity and in direction) were also monitored in the same time by the Meteo-France meteorological station of Takaroa (atoll close from Takapoto). Physical parameters (temperature, salinity and O₂ concentration) of water were also recorded by the SRM Takapoto field laboratory with the help of an HYDROLAB multi-parameters probe.

Water for suspended particulate matter (triplicate of 5 l) was pumped once in a week at the same hour (14 h), pre-filtered at 200 µm, collected in dark bottle and brought back to the laboratory as fast as possible. Seston were collected by filtration on pre-combusted (500 °C for 4h) and pre-weighed 47 mm Whatman GF/C filters. After copiously rinsing with isotonic ammonium formate in order to remove salt, filters were dried overnight at 60 °C and weighed to give the total particulate matter retained on the filter (TPM in mg dry wt l⁻¹). The weight of ash remaining after 4 h of combustion at 500 °C gave the value of mineral matter (PIM in mg ash dry wt liter⁻¹) and losses by ignition gave the organic matter (POM in mg ash free dry wt l⁻¹).

2.2. Growth measurement

Biological material :

Growth rates were estimated by sacrificial sampling of pearl oysters in a known population, cultivated at a single station (station 1) in the SW extremity of Takapoto lagoon (see Fig. 1). Farming of these pearl oysters was conducted by the SRM field laboratory. Cultivation technique was very close from those commonly used in professional farms. Suspended long-lines were immersed at 7 m deep. Pearl oysters were "ear hanging" on downline at low density (< 20 oysters m^{-3}) except for young oysters (age group 1) which were arranged in lantern nets where density was somewhat higher. Growth was followed for one year (from March 1997 to April 1998) on three age groups (pseudo-cohorts) : 1, 2 and 3 year-old at the beginning of the study. The age groups were estimated based on the last summer spat fall. Error in estimation was ± 2 months based on uncertainty in time of spat settlement.

Sampling scheme :

A systematic sampling scheme was conducted : every 15 days and during 1 year, 40 individuals were randomly sampled in each age group, cleaned of the fouling organisms and sent by aircraft to Tahiti island for measurement, weighing and dissection.

Biometry (see Table 1):

Concerning the shell, measurements were made according to Hynd (1955). Dry shell weight (both valves) was obtained after drying at 60 °C for 72 h. Growth striations, which appear on cleaned shells, were also counted, because an interesting relationship with the age was suspected. This counting was realised every 4 months on a sub-sample in each pearl oysters age group. If growth striations can be easily counted on young cleaned shells, a problem occurred for larger oysters because shells were often worn in the vicinity of the umbo. In this case, we designated an area where counting was impossible and we used, as substitute for this area, the average counting of an equivalent area realised on younger pearl oysters, assuming that inter-annual variations were insignificant.

Concerning the flesh, total wet tissue weight (after 5 min of draining) and total dry tissue weight (after a complete freeze-drying cycle) were measured on each individual. After dissection, the same operation was conducted, separately, on adductor muscle, retractor muscle, gills (+mantle) and gonad (+digestive gland). Tissue water content was determined by difference between wet and dry weights and ash content was obtained on a sub-sample ($n=10$) every 15 days after ignition in a muffle furnace at 500 °C during 12 h.

2.3. Statistical analyses

Three kinds of statistical analyses were performed : (1) estimation of several useful length-weight relationships ; (2) calculation of tissue and shell growth rates and (3) fitting of empirical growth models.

Length-weight relationships were estimated according to the equation $Y=aX^b$. These relationships are very useful to compare data from different studies. Absolute growth rates, i.e. the cumulative increase with respect to time, were calculated as the slope of the regression of growth data vs time, assuming that growth was nearly linear for short period.

Cumulating all the data from the three age-groups, growth in both shell and tissue was expressed as a function of age, determined with empirical growth models fitted on height and weight. To reach this aim, four kinds of models were used : (1) annual shell growth in length was described by the Von Bertalanffy model (1938), already applied on growth curves in *Pinctada* genus : $Y = Y_{\infty} [1 - e^{-k(t-t_0)}] = Y_{\infty} [1 - e^{-(a-kt)}]$;

(2) annual shell / tissue growth in weight was directly derived from the previous equation by using the extended Von Bertalanffy model (Richards, 1959) : $Y = Y_{\infty} [1 - e^{-k(t-t_0)}]^b$;

(3) results of the extended Von Bertalanffy model were compared with results obtained by a logistic model, which is a derivation of the general model proposed by Schnute and Richards (1990) : $Y = Y_{\infty} / [1 - e^{-(a-kt)}]$;

(4) seasonal variations observed in tissue weight were described by incorporating oscillation (e.g. Buestel and Laurec, 1976; Pauly and Gaschütz, 1979; Bodoy, 1982; Buestel et al., 1987) into the previous logistic model, as follows : $Y = Y_{\infty} / [1 - e^{(a-kt - \alpha \sin \omega(t-\phi))}]$

In these equations, Y represents the height or the weight at time t , Y_{∞} the asymptotic (or theoretical maximum) length or weight, t the age in months, k the rate at which asymptotic value is approached, b the exponent value from the shell length-weight relationship, α the amplitude of the oscillation, ϕ phase displacement which permit to locate the annual slowing down in growth ($\omega = 2\pi/12$ when t is expressed in month), t_0 and a are adjustment parameters without any biological meanings.

These models were fitted by the Marquardt algorithm within Statgraphic's plus Software. Von Bertalanffy model was used in our work in order to permit comparison with other previous works (e.g. Sims, 1994) ; however, extended models (Schnute and Richards, 1990) are, as a general case, more appropriate (Roff, 1980).

3. RESULTS

3.1. Environmental parameters

Long time data sets of water parameters (temperature, salinity and oxygen concentration, POM and PIM, Fig. 2) showed that annual variations were nearly insignificant except for water temperature, which followed a clear seasonal pattern, between 26 °C in August and 31 °C in March, strongly linked with the air temperature (Fig. 2a). Salinity varied from 38 to 42 ‰ with a hazy seasonal pattern. Oxygen concentration was fairly constant around 6 ml l⁻¹ (Fig. 2b). Mineral and organic particulate matter (PIM and POM, mg l⁻¹; Fig. 2c and Fig. 2d) varied between 0.20 and 0.90 mg l⁻¹ with a turbulent pattern strongly related to wind speed variations, especially for PIM (Fig. 2c).

3.2. Biometry and length-weight relationships

Biometry relationships were described by several regressions (Table 2). As a general case, coefficients of determination (R²) were very high, indicating that model fitting was highly significant.

Concerning shell measurements, the power exponent of each equation was very close to 1.00 demonstrating that growth in length, in breadth and in thickness was fairly isometric. The nacreous height (H_{nac}) and breadth (B_{nac}) represented, respectively, 75 % and 78 % of the total height H (H_{nac}=0.75 H and B_{nac}=0.78 H). The length-weight relationships showed that dry shell weight (W_{shell}) scaled with (height dimensions)³, whereas dry tissue weight (W_{Tissue}) scaled with (height dimensions)^{2.78}. Organ measurements showed that tissue growth was nearly isometric with power exponent between 0.85 and 1.10, except for retractor muscle (exponent *b*-values equals to 0.60). Dry shell weight was nearly 24 times greater than dry tissue weight. The relative contribution of each organ to the entire tissue weight was roughly equal to 46 % for muscle, 32 % for gill (+mantle) and 21 % for gonad (+ digestive gland).

The shell increment (S) showed a very regular increase with the pearl oyster age, described by a linear regression (Table 2). The slope *a* was equal to 1.18 (± 0.036 SE) striations by months, i.e. one striation increment every 26 days. The intercept *b* was significantly different from 0 (*b* = 16.58 ± 1.13 SE) which shows that striations increment would be higher during the first year of the pearl oyster life cycle. Thus, striations counting appeared to be a reliable method to determine the age for a given pearl oyster : Age (in months) was roughly equal to (S-16.58)/1.18, except for very young oyster (< 1 year-old).

3.3. Growth rates

Shell growth :

As a general case, no seasonal trend was observed in shell growth (Fig. 3). Table 3 showed that, from March 1997 to April 1998, height (H) increased steadily from 44.0 to 76.5 mm for age group 1, from 97.6 to 113.3 mm for age group 2 and from 117.1 to 126.8 for age group 3. Since seasonal trend was insignificant, the daily mean increment in shell height, equal to $95 \mu\text{m d}^{-1}$ for age group 1, $34 \mu\text{m d}^{-1}$ for age group 2 and $24 \mu\text{m d}^{-1}$ for age group 3 (Table 4), showed that shell increment decreased with the age of the pearl oyster. The same observation is also valuable for shell thickness (T) : the nacreous deposition was around $7.2 \mu\text{m d}^{-1}$ for age group 1 and decreased to $3.1 \mu\text{m d}^{-1}$ for age group 3 (Table 4). On the other hand, pattern followed by dry shell weight (W_{Shell}) was quite different : increments in shell weight were higher in older oysters (from 109 mg d^{-1} for age group 1 to 175 mg d^{-1} for age group 3, Table 4).

Tissue growth :

Tissue growth showed a different pattern than shell growth. Firstly, tissue growth exhibited a seasonal trend (Table 3) : maximal rate was observed during fresh season (from May to November 97), whereas growth was insignificant during warm season (from December 97 to March 98). In this case, estimation of a mean daily increment in tissue weight becomes less accurate. Secondly, tissue was affected by numerous temporal short-scales variations, especially in the age groups 2 and 3. These variations were mainly observed on gonad compartment, especially in > 2 year-old pearl oysters (Fig. 3).

3.4. Empirical growth models

In order to explain growth in relation with the pearl oyster age, several models were estimated. As a general case, it appeared that the Von Bertalanffy equation described accurately shell growth in length, whereas the logistic form provided better fits for shell and tissue growth in weight.

Shell growth :

The Von Bertalanffy equation, fitted to shell height data (Fig. 3a), was the following :

$$H = 160.5 (1 - e^{-0.038 (t-3.73)}) \text{ with } R^2=0.96$$

This model provided an estimate of the asymptotic height H_{∞} and an estimate of the growth parameter k . H_{∞} was found to be equal to $160.5 \text{ mm} (\pm 6.6 \text{ SE})$, whereas k was equal to $0.038 \text{ month}^{-1} (\pm 0.004 \text{ SE})$. The t_0

value was found to be 3.73 months (± 0.66 SE). Nevertheless, fitting was not good for young oysters and a logistic model would be more appropriate (Fig. 3a). The equation became the following :

$$H = 129.2 / (1 + e^{(2.31 - 0.127 t)}) \text{ with } R^2=0.97$$

Adequacy between model and observations was better than previously ($R^2=0.97$) especially for young oyster.

The asymptotic value for shell height, H_∞ , became lower : 129.2 mm (± 4.3 SE).

The extended Von Bertalanffy equation was applied to shell weight data, by using the exponent value of the shell length-weight relationship ($b=3$, see Table 2). The equation, described on Fig. 3b, became :

$$W_{\text{shell}} = 292.5 (1 - e^{-0.06 (t-8.73)})^3 \text{ with } R^2=0.99$$

The theoretical asymptotic mean value for shell weight, $W_{\text{shell } \infty}$, was equal to 292.5 g (± 12.0 SE), the growth parameter k was equal to 0.061 month⁻¹ (± 0.004 SE) and the adjustment parameter, t_0 , was equal to 8.73 months (± 0.66 SE). As previously, a logistic curve exhibited a better adjustment (Fig. 3b), especially for young individuals, and the new equation was :

$$W_{\text{shell}} = 241.7 / (1 + e^{(2.10 - 0.110 t)}) \text{ with } R^2=0.98.$$

The asymptotic value for shell weight became lower : 241.7 g (± 6.3 SE).

Tissue growth :

As previously, data suggest a sigmoidal form, so that logistic model would provide an accurate fit. Preliminary results given by fitting the extended Von Bertalanffy model are summarised in the following equation (see Fig. 3c) :

$$W_{\text{tissue}} = 13.9 (1 - e^{-0.038 (t-3.919)})^{2.78} \text{ with } R^2=0.95$$

The theoretical mean value for tissue weight, $W_{\text{Tissue } \infty}$, was equal to 13.9 g (± 0.6 SE), $k = 0.038$ month⁻¹ (± 0.004 SE) and $t_0 = 3.92$ months (± 0.75 SE). Model adequacy was not satisfactory, especially for old oysters ; in that $W_{\text{Tissue } \infty}$ was over-estimated. Since data showed repetitive seasonal oscillations, a more complete model incorporating seasonal effect was preferable. Then, the equation became (see Fig. 3c) :

$$W_{\text{tissue}} = 6.9 / (1 + e^{(5.58 - 0.208 t - 0.435 \sin(2\pi/12 (t-1.427))}) \text{ with } R^2=0.98$$

This new model exhibited a very good fitting with the data. In that case, asymptotic value $W_{\text{tissue } \infty}$ was 6.9 g (± 0.1 SE). Rate at which this asymptotic value is approached was equal to 0.208 month⁻¹ (± 0.010 SE) and

α , a measure of the oscillation amplitude, was equal to 0.435 g (\pm 0.061 SE). Phase displacement averaged 1.427 month (\pm 0.239 SE). Adequacy between observations and predictions was good ($R^2=0.98$).

Individual organ growth followed similar patterns and the same kind of model was applied. Parameter estimates of all these models are given in Table 5. Models for adductor muscle and gill exhibited a high reliability ($R^2 \sim 0.98$, Fig. 3d and Fig. 3e). Gonad (+digestive gland) showed numerous small-scale variations (Fig. 3f) which affected adequacy between data and model, as indicated by larger SE and lower R^2 values (Table 5). Asymptotic values for adductor muscle, retractor muscle, gill and gonad were, respectively, equal to 2.84, 0.42, 2.00 and 1.39 g. The sum of this 4 asymptotic values was in total agreement with $W_{\text{Tissue}\infty}$ obtained previously.

4. DISCUSSION

4.1. Lagoon environment variability

Polynesian lagoon water, and especially Takapoto lagoon, are characterised by very low POM and PIM concentrations in comparison with other shellfish areas where bivalve food resources have been examined. In Polynesian water, POM was well-studied concerning its taxinomic composition (e.g. Charpy, 1996; Charpy et al., 1997 ; Charpy and Blanchot, 1998), whereas less is known about its annual variation. This work showed that POM is available all around the year. Thus, no period of starvation occurs in pearl oyster populations. Temperature was the only one parameter to show seasonal variations. But amplitude of these variations was low ($< 5^{\circ}\text{C}$) and minimal value (reached in August) was 26°C , so that this parameter could not constitute an inhibitor factor for growth, as it is the case in temperate environments. Since oxygen concentration and salinity were also very constant, no season is unfavourable to pearl oyster growth. Lagoon environment stability would imply regular growth of pearl oyster.

4.2. Pearl oyster growth

The growth of a bivalve is the total result of many interacting endogenous and exogenous factors. Among endogenous factors, age is presumably the most important. Among exogenous factors, we can distinct those which are related to environment (food supply and temperature) and those which are related to farming conditions (density, depth, trophic competitors).

Endogenous factors

Growth rates in shell or tissue are directly related to bivalve age. Growth in *P. margaritifera* was fast up to the third year and thereafter it became reduced. Most of the studies (e.g. Nalluchinnappan et al., 1982 ; Nasr, 1984 ; Gervis and Sims, 1992 ; Numaguchi, 1994) who investigated pearl oyster growth have lead to the same conclusion. This decrease with age is strongly linked with the progressive investment in reproduction, since the part of the scope for growth which is allocated to reproduction (called the reproductive effort, ER, Thompson, 1984) is lost for shell or tissue growth.

Among the various parameters of growth presented in this work, those concerning shell thickness and nacreous deposition deserves a special care. Increment in nacreous deposition, which was equal to $7.2 \mu\text{m days}^{-1}$ during the second year of the life cycle (in total agreement with Caseiro, 1993), decreased dramatically with the age of pearl oyster and reached a mean value of $3.1 \mu\text{m days}^{-1}$ during the fourth year of the life cycle. This result is full of interest for two reasons.

Firstly, for pearl seeding operations and farming management, it implies that the sooner the nucleus is implanted, the greater is the rate of nacreous deposition on this nucleus, and shorter is the time to obtain a marketable pearl for farmers.

Secondly, for biologists, it implies that heel depth (shell thickness) does not constitute a good indicator for age determination as reported by Tranter (1958), Thielley (1993) or Sims (1993, 1994). This work showed effectively that the best non destructive indicator for age determination in *P. margaritifera* in Polynesian water was presumably the growth striations, since annual growth rings (Pandya, 1976) are not well-defined in *P. margaritifera*. The increment in striation (approx. 1 month^{-1} for > 1 year-old pearl oyster) could be related to the monthly periodicity of lunar cycle since in the lagoon environment no other monthly stresses are evident (tide are insignificant and pearl oyster are never emerged). Tagging experiments would confirm this interesting assumption and further works should be performed in that way.

Environmental factors

Previous studies of growth of Pteriidae in tropical environment (Coeroli et al., 1984; Gervis and Sims, 1992; Sims, 1993 and 1994; Saucedo and Monteforte, 1997) were restricted to study the shell growth (in length or in weight), and observed no seasonal trend. On the contrary, our study showed that seasonal variations occurred, but only in tissue growth : tissue growth slowed in austral summer (warm season), especially for >2 year-old pearl oysters (an observation in agreement with Leduc (1997) who measured a decline in tissue weight in 3 year-old pearl oysters inhabiting an other Polynesian lagoon).

Bivalve growth increments are known to be strongly influenced by environmental conditions such as food supply and water temperature (e.g. Thompson, 1984). In our study, the slowing down in growth observed in summer could not be related to food concentration (POM) since this factor remained relatively constant. As a general case, in temperate regions, a rise in temperature is favourable for bivalve growth (e.g. Richardson et al., 1982), but in an environment of low food availability, a rise in temperature which results in an increased

metabolic energy expenditure may cause a reduction in growth rate (Mann, 1979 ; Bayne and Worall, 1980 ; Sebens, 1982) as it may be the case in our study. For example, working in the Gulf of Kutch, Gokhale et al. (1954) assumed that pearl oysters *P. fucata* grew vigorously in winter months and ceased in summer. This observation was confirmed by Pandya (1976) who reported that growth rate was higher between 19 and 28°C than between 28 to 32°C. Such decreases at higher temperatures has also been shown for other species (e.g. Laing et al., 1987 ; del Rio-portilla et al., 1992). In that respect, warm season may constitute a risky period for pearl oysters culture, and a special care must be taken, especially for El niño years.

Farming conditions

Depth, stocking density and bio-fouling are also known to modify pearl oysters growth (Chellam, 1978; Nasr, 1984; Elnaeim, 1984; Buestel et al., 1995; Leduc, 1997). We tried to maintain control on these three factors : depth was fixed, density was low and pearl oysters were cleaned periodically of bio-fouling.

Bad farming conditions (especially high density) may be the explanation of mortality events. An episode of high mortality was observed in 1985-1986 in several Polynesian lagoons. At this time, *P. margaritifera* was cultivated on tables at higher densities than are now employed. High density combined with high temperature and low renewal of water may cause significant mortality in culture. Such an explanation have already been used to explain mortality of *P. fucata* in Ohmura Bay in 1976 (Numaguchi, 1994). To give a better understanding, a depletion model (e.g. Fréchette et al., 1989; Incze et al., 1981) is at the present time in construction, and will be the aim of a further paper.

4.3. Comparison with other species and/or with other area

Growth data and especially those concerning shell are important for pearl farming since they give useful information concerning (1) pearl oysters health in culture system ; (2) deposition rate of nacreous matter on the shell but also on the implanted nucleus ; and (3) suitability of potential pearl farming sites. In that respect, comparing growth performance, for several pearl oyster species and/or for several areas, is full of interest.

If growth rate in tissue weight are poorly documented for the genus *Pinctada* (Elnaeim, 1984 ; Leduc, 1997), data concerning shell growth are more abundant (Chellam, 1978; Elnaeim, 1984; Nasr, 1984; Coeroli et al.,

1984; Chellam, 1988; Sims, 1993, 1994; Buestel et al., 1995; Leduc, 1997). Table 6 gives an overview of the existing knowledge concerning shell growth rates in Pteriidae, and permits comparison. Growth rate in *P. margaritifera* was higher than those measured in *P. fucata* or in *P. mazatlanica*. Unfortunately, no comparable data are available on *P. maxima* which certainly exhibits the highest growth rate of the *Pinctada* genus (Gervis and Sims, 1992 ; Yukihiro et al., 1998). Concerning *P. margaritifera* var *cumingi*, the highest shell growth rate was obtained in Takapoto atoll : the assumption of « dwarfism » of the pearl oyster which inhabit the Takapoto lagoon need certainly to be moderate.

In some cases, Von Bertalanffy model had been applied on the available data (Table 7), and the parameters H_{∞} and k of the equation are also useful in comparing intra or interspecific growth performance.

Concerning interspecific performance, the lowest H_{∞} -value were obtained in *P. fucata*, in *P. mazatlanica* and in *P. margaritifera* var. *erythraensis* which respectively averaged 79.3, 84.9 and 125.5 mm. On the other side, these three smaller species exhibit faster growth rates (higher k -values) and their life expectancy are shorter with a life of only approx. 3-4 years (Gervis and Sims, 1992). The highest H_{∞} -values may presumably obtained for *P. maxima* (Yukihiro et al., 1998, reported maximum shell height above 200 mm) but Von Bertalanffy parameters are not yet available on this species. *P. margaritifera* var. *cumingi* showed intermediary H_{∞} and k -values, respectively around 160 mm and 0.45 mm y^{-1} .

Variability in intraspecific performances is also significant, especially for *P. margaritifera* var. *cumingi* (Table 7). The k -value varied between 0.35 and $0.76 \text{ mm year}^{-1}$ and the L_{∞} -value between 148.9 and 181.7 mm. The main source of these variations is presumably the pearl farming sites : Sims (1994) worked in Cook Islands, Leduc (1997) in Rangiroa atoll and Coeroli et al. (1984) in Takapoto atoll. In a very recent work, Yukihiro et al. (1998) measured maximal length around 150 mm in Australia waters. This tends to show that *P. margaritifera* growth is presumably different from an atoll to an other. In that respect, variability in growth between lagoons need to be studied and would certainly bring very useful information concerning (1) the relationships between growth and environmental parameters ; and (2) the most suitable sites for pearl oyster farming. To reach this aim, growth would be studied not only for external parameters (height or striation), but also for internal ones (tissue and maturity).

Finally, we can conclude that the black-lipped pearl oyster *Pinctada margaritifera* var. *cumingi* shows relative fast growth in Polynesian waters, although food suspension (POM) is rather low. This ability to grow fast in poor environment is permitted by high pumping activity (see Pouvreau et al., 1999a and 1999b for *P. margaritifera* in Polynesian waters). Other Pteriidae have also developed the same ability (see Yukihiro et al., 1998) : for example, *P. maxima*, which typically inhabits area characterised by higher amount of suspended particulate matter than those of *P. margaritifera*, can also exhibit high efficiency to grow under low food suspensions. In that respect, *P. maxima* and presumably other species as *P. margaritifera* var. *erythraensis*, may also exhibit fast growth in Polynesian waters and, then, may constitute potential candidates for further Polynesian diversification projects.

Acknowledgements

This work, entitled “Project CREM”, was carried out at the IFREMER Pacific Oceanological Centre (Tahiti) and was supported by the “Programme Général de Recherche sur la Nacre” and by a financial help of the Research Ministry. At the end of this work, we would like to thank all the person from the Tahiti - IFREMER centre and especially S. Robert, G. Jonquière, A. Bennett and X. Caisey for their numerous help during CREM project. We want also to thank all the SRM team for their field assistance on Takapoto atoll.

Tables

Table 1 : Parameters, acronyms, and units used in this study for growth measurements on *Pinctada margaritifera*.

Parameters	Acronyms	Measurements	Units
<u>Shell measurements</u>			
Total length (dorso-ventral axis)	L	From the heel to the furthest edge of non-nacreous border, excluding digitate processes and taking into account the curve of the right shell	mm
Total height or diameter (dorso-ventral axis)	H	From the heel to the furthest edge of non-nacreous border, excluding digitate processes without taking into account the curve of the right shell	mm
Height of nacreous layer (dorso-ventral axis)	H _{nac}	From the heel to the furthest edge of nacreous border without taking into account the curve of the right shell	mm
Breadth of nacreous layer (antero-posterior axis)	B _{nac}	From the anterior edge of nacreous border to the posterior one parallel to the heel and without taking into account the curve of the right shell	mm
Thickness of shell	T	Thickness of the valve at the hinge line on dissected valve	mm
External growth striations	S	Number of concentric lines counted on cleaned shell	
Shell weight	W _{shell}	Dry shell weight (both valves) obtained after drying at 60°C for 72 h	g
<u>Flesh measurements</u>			
Tissue weight	W _{tissue}	Dry soft tissue weight obtained after a complete freeze-drying cycle	g
Adductor muscle weight	W _{mu1}	Dry weight of adductor muscle obtained after a complete freeze-drying cycle	g
Retractor muscle weight	W _{mu2}	Dry weight of retractor muscle obtained after a complete freeze-drying cycle	g
Gills weight	W _{gill}	Dry weight of gills (+mantle) obtained after a complete freeze-drying cycle	g
Gonad weight	W _{gonad}	Dry weight of gonad (+digestive gland) obtained after a complete freeze-drying cycle	g
