Abstract:

The ECOLOPHY experiments aimed at investigating physical exchanges between coastal and open sea. They were carried out in June and December 2005 over the shelf-break in the North-eastern part of the Gulf of Lions (Northwestern Mediterranean Sea). This area is considered to be the generation zone for the eddy and meandering structures of the Northern Current (NC). The objective of the present work is to examine mesoscale variability of this coastal slope current in the light of available data. Numerical modeling is used to support the field data analysis. ADCP current measurements over a one-year period show that mesoscale activity is maximal in late winter, correlating with the seasonal variability of the NC and, also, partly with local winds. Measured currents exhibit mesoscale fluctuations with periods ranging from 3 to 30 days, in agreement with previous analyses. Fluctuations of periods longer than 10 days are found to be mainly oriented in the direction of the mean current, whereas more frequently observed high frequency fluctuations tend to be oriented cross-slope, suggesting a relationship with the NC mesoscale meandering. Moreover, trajectories of surdrift buoys launched in the NC vein exhibit mesoscale phenomena, such as current meanders or eddies and on-shelf intrusions. Numerical modeling provides a synoptic point of view and is used hereafter to support physical interpretation of punctual eulerian or lagrangian measurements. Therefore, modeled hydrodynamic fields are used to analyze surdrift buoy trajectories and computed vertically averaged current and Ertel potential vorticity provide a better understanding of these behaviors.

Keywords: Northwestern Mediterranean Sea; Gulf of Lions; Northern Current; Slope current; Mesoscale variability; Numerical modeling

1 Introduction

1.1 Background

Coastal slope currents exhibit unstable behavior due to barotropic and baroclinic instabilities (Middleton and Cirano, 1999; Mysak et al., 1981), which generate mesoscale eddies and meanders resulting from number of interactions (wind forcing, tides, buoyancy, bathymetry ...). This kind of mechanisms can play a role on the current intrusions across the continental shelf and were investigated in a number of regions for the Kuroshio (Guo et al. 2006, Miyazawa et al. 2004) and for the Gulf Stream (Blanton et al. 1981, Brooks and Bane 1983). In our area of interest, in the microtidal Mediterranean Sea, process-oriented investigations have been performed on the curvated Catalan slope current along Ebro delta site's narrow shelf (Gjevik et al. 2002; Xing and Davies 2002) and of the Gulf of Lions (Flexas et al. 2002; Flexas et al. 2004). These previous investigations especially pointed the importance of the wind forcing, inertial motion and complex bathymetry on the cross-shelf fluxes in microtidal sea. The purpose of this paper is to examine the mesoscale slope current variability observed in the continental

1
2
3
4 slope of the eastern Gulf of Lions during the ECOLOPHY cruises with help of
5
6 numerical simulation. In our case, a realistic wind forcing was made available,
7
8 allowing investigation of the origin of eddy and meander structure of the NC with
9
10 help of a high-resolution model.
11
12
13
14

15 The Northern Current (NC) is the northern branch of the general cyclonic
16
17 circulation in the western Mediterranean basin, where relatively fresh surface
18
19 water flows from the Atlantic Ocean (Atlantic Water, hereafter called AW)
20
21 through the Gibraltar Strait into the semi-enclosed Mediterranean Sea, to
22
23 compensate for evaporation losses. This current results from the junction of the
24
25 Western Corsican Current (WCC), flowing north-eastward from the Algerian
26
27 Basin, and the Eastern Corsican Current (ECC) arising from the Tyrrhenian Sea
28
29 through the Channel of Corsica (Astraldi and Gasparini, 1992). The NC is a slope
30
31 current flowing along the coast from the Ligurian Sea up to the Balearic Sea.
32
33 Several cruises performed over the two last decades have shown that this current
34
35 exhibits a seasonal variability with maximum flux in winter, ranging from a
36
37 minimum of 0.2 Sv ($1 \text{ Sv} = 1.10^6 \text{ m}^3 \cdot \text{s}^{-1}$) in summer to a maximum of 1.2 Sv in
38
39 winter across a transect off Marseille (Lapouyade and Durrieu de Madron, 2001)
40
41 and from 1 Sv to 1.6 Sv between 0 and 300 dbar from autumn to summer off the
42
43 city of Nice (Albérola et al. 1995). It is a wide (ca. 50 km) and shallow (down to
44
45 250 m depth) current in summer; it becomes narrower (ca. 30 km) and deeper (ca.
46
47 450 m) in winter; with a maximum velocity near the surface ($30 - 50 \text{ cm} \cdot \text{s}^{-1}$), then
48
49 linearly decreasing with depth.
50
51
52
53
54
55

56 This current generally flows to the south of France, along the deepest half of
57
58 the continental slope of the Gulf of Lions (GoL) where it bounds and controls the
59
60 shelf circulation. Depending mainly on wind forcing conditions, it may intrude on
61
62
63
64
65

1
2
3
4 the continental shelf, especially in the eastern, and sometimes in the central, parts
5
6 of the gulf (Millot, 1979; Millot and Wald, 1980; Estournel et al, 2003; Petrenko,
7
8 2003). The complex GoL continental slope is intersected by a number of irregular
9
10 canyons (**Fig. 1**). These irregularities, considering the potential vorticity
11
12 conservation, can generate mesoscale current features, such as meanders,
13
14 filaments and secondary eddies on the inner side of the NC (Flexas et al., 2002).
15
16 Therefore, water exchanges across the GoL continental slope are influenced by
17
18 mesoscale instabilities of the NC, and by strong northwestern (Tramontane) and
19
20 northern (Mistral) continental winds, which generate classical oceanographic
21
22 small-scale features such as coastal up- and down-wellings along coasts (Millot,
23
24 1979) and inertial motions (Petrenko, 2003). Water exchanges are also influenced
25
26 by dense water cascading induced by wintertime continental winds (Dufau-
27
28 Jullian et al., 2004; Guarracino et al., 2006). However this last process, acting
29
30 with an interannual variability is not in the purpose of the present study.

36

37 ***1.2 Evidence of mesoscale current variability***

38
39 The NC displays intense mesoscale variability, which mainly appears as
40
41 meanders and anticyclonic eddies occurring at the jet edge over the upper
42
43 continental slope, exhibiting different noticeable length scales. These meanders
44
45 have a wide range of wavelengths (some 10 to 100 km), phase speeds of 10 to 20
46
47 km.day⁻¹ (Alb rola et al., 1995) and major variability occurs within a 2- to 10-day
48
49 period. Durrieu de Madron et al. (1999) and Lapouyade and Durrieu de Madron
50
51 (2001) observed a seasonal signal with stronger mesoscale variability in winter
52
53 than in summer, when other authors (Taupier-Letage and Millot, 1986) reported
54
55 significant mesoscale activity during an extended winter from December to May,
56
57 highlighting a good correlation between maximum momentum energy in the NC
58
59
60
61
62
63
64
65

1
2
3
4 and a high mesoscale variability. Although major mesoscale activity is usually
5
6 assumed to occur in late autumn and decrease in late winter, meanders have been
7
8 observed from satellite images throughout the whole year (Millot, 1999).
9

10
11 Current records obtained near the bottom of the GoL continental slope revealed
12
13 that topographic waves propagate at a period of about 8 days with a mean phase
14
15 speed of 11 cm.s^{-1} , the bottom slope acting as a wave-guide (Millot, 1985).
16
17 According to *in situ* data recovered off Nice during the PRIMO-0 (December
18
19 1990 – May 1991), PROLIG-2 and PROS-6 experiments (May – December
20
21 1985), in a location just upstream from the entrance of the GoL (Albérola et al.,
22
23 1995; Sammari et al., 1995), two frequency ranges appeared in winter: a more
24
25 energetic 10- to 20-day band and a weaker 3- to 6-day band. During the MATER
26
27 HFF experiment (March – May 1997) current observations at 240-, 650- and
28
29 1230-m and hydrographic data showed that meanders occupied a large part of the
30
31 water column (Flexas et al., 2002). From these data, two main peaks were
32
33 observed with different characteristics: along-slope fluctuations with a 7-day
34
35 period and isotropic fluctuations with a 3.5-day period. Using current
36
37 measurements and analytical models, Flexas et al. (2002) proposed that the large
38
39 NC meanders with a 10- to 40-day period and those with a 7-day period could be
40
41 due to baroclinic instabilities. The case of the 3.5-day period fluctuations was
42
43 investigated in detail in Flexas et al. (2004) who indicated that barotropic
44
45 instability was one of the possible mechanisms (co-existing with baroclinic-type
46
47 instabilities) responsible for such oscillations. According to Flexas et al. (2002),
48
49 the 7- and 3.5-day period current fluctuations probably reflect propagating
50
51 topographic Rossby waves (Pedlosky, 1979).

1.3 Present study

The ECOLOPHY experiment is part of the French National Atmosphere–Ocean program (Programme National Atmosphere – Océan à Multiéchelles). This research project was initiated to improve the understanding of NC variability as a major process in water exchange across the GoL shelf. In order to investigate the seasonal and mesoscale variability of the NC, the ECOLOPHY experiments were conducted in spring and autumn 2005 in the southeastern part of the GoL, over the shelf-break (**Fig. 1**). This area is considered to be the generation zone for eddy and meander current structures of the NC (Flexas et al., 2002). The sampled zone was formed by an upstream coarse grid providing cross-NC measurements at the entrance of the GoL and by a downstream higher-resolution grid, located on the shelf-break, to capture fine eddy structures.

The objective of the present work is to examine the mesoscale variability based on moored ADCP current records, ship-borne hydrological and currents measurements, and drifting buoy trajectories. A high-resolution model was also used to investigate the origin of eddy and meander structure of the NC. Finally, a discussion of results and subsequent investigations are presented.

2 Materials and methods

2.1 Observations

The two ECOLOPHY experiments were conducted in the southeastern part of the GoL, in a first phase (hereafter called EXP-1), from May 28 to June 5, 2005 and in a second phase (EXP-2) from December 1 to 11, 2005. Hydrodynamic features were thus documented for different weather and stratification conditions. Hydrological data were collected using CTD (Conductivity Temperature Depth) and XBT (Expendable Bathythermograph) probes at stations indicated on **Fig. 1**. Vertical profiles of horizontal currents were measured along the R/V *Tethys II*

1
2
3
4 track using an ADCP profiler mounted on its hull. Description of the circulation
5
6 features was completed using Lagrangian drifter trajectories, providing long time
7
8 series of current measurements in the NC. Moreover, two fixed moorings (called
9
10 M1 and M2) were deployed on the shelf from May 28 to December 1, 2005 and
11
12 again until June 19, 2006. These continuous measurements provided valuable
13
14 information concerning the variability of currents over the upper slope.
15
16
17

18 **2.1.1 Drifter tracks**

19
20 During the two experiments, 24 surface floats anchored at 50 or 75 m depths
21
22 were released off Cape Sicié, inside the NC vein. 16 buoys were launched on 3
23
24 consecutive legs during EXP-1 and 8 others on 2 legs during EXP-2. Surdrift (SC-
25
26 40 type during EXP-1 and SVP type during EXP-2) positions were collected using
27
28 GPS then transmitted via Argos to the orbiting satellites. The validated space-time
29
30 series of drifter locations were linearly interpolated over time to obtain the
31
32 trajectories with a 1h time-step. Release dates and locations are given in **Table 1**.
33
34
35

36
37 Lagrangian velocities were computed from drifting buoys successive positions.
38
39 A Lanczos filter with a cutoff frequency of 40 hr was applied on validated
40
41 velocity data in order to remove inertial oscillations (periods of about 17.5 hr) and
42
43 other shorter periods. Surdrifts are not exactly Lagrangian because the drag
44
45 exerted on the surface buoy and on the cable linking the buoy to the deep drogue
46
47 contributes to their displacement. However, this drag effect is negligible
48
49 compared to the drag exerted on the drogue itself. Tests were also performed
50
51 using acceleration values to detect possible loss of drogues or trawling. In such
52
53 cases, trajectories were terminated. This detection of drogue loss is a crucial point
54
55 because if a drogue breaks, the trajectory will reflect surface wind-induced
56
57 currents and not depth currents. Surdrift lifetimes are given in **Table 1**.
58
59
60
61
62
63
64
65

2.1.2 Current data

Current data were obtained in two different ways. First, vertical current profiles were collected from an ADCP current profiler (RDI broadband 150 kHz) mounted on the hull of the R/V *Tethys II*, along tracks shown in figure 1. Continuous measurements were made during all cruises that gave a quasi-synoptic view of the circulation over the entire water column. The time spend by the ship to performed each section is about 7h for T1 and T3 and 5h for T2. The chosen settings were: 60 cells, 4 m depth bins, 1-minute ensemble average, and bottom tracking when possible. ADCP data analysis was performed by the French INSU (Institut National des Sciences de l'Univers, <http://saved.dt.insu.cnrs.fr>) staff. The shallowest reliable measurement is at 10 m depth and the deepest one is at ca. 200 m.

Second, two Broadband RDI 75 kHz ADCP moorings called M1 and M2 were deployed on the bottom at depths of 400 and 200 m, respectively, next to the shelf break, on the western flank of adjacent canyons' heads (**Fig. 1**). The settings used were: 50 cells and 30-minute ensemble averages for both moorings and 8 m depth bins for M1 and 4 m depth bins for M2. These moorings provided current measurements at given points from the end of May 2005 to June 2006.

2.1.3 Hydrological data

During the two ECOLOPHY cruises, 156 CTD stations or XBT casts were performed along three transects (see **Fig. 1**). The first hydrological network (EXP-1) included 77 CTD and XBT stations (May 28 – June 5, 2005). The second hydrological network (EXP-2) comprised 79 CTD and XBT stations (December 1–11, 2005). This kind of measurement does not provide an exact synoptic view of hydrological features regarding the higher frequency variability of the NC. Nevertheless, reconstituted temperature, salinity and density fields along sections

1
2
3
4 from hydrological measurements averaged over the duration of the surveys will be
5
6 used to analyze its mean behavior.
7
8

9 **2.2 Numerical model**

10 Modeling was performed using the MARS-3D (3D hydrodynamic Model for
11 Applications at Regional Scales) code developed at IFREMER (Lazure and
12 Dumas, 2007). A description of the model configuration for the Northwestern
13 Mediterranean Sea is given in André et al. (2005). Primitive equations were
14 solved applying the Boussinesq approximation, hydrostatic equilibrium and
15 incompressibility. This free-surface model, based on the proposal of Blumberg
16 and Mellor (1987), uses an original semi-implicit and iterative time-step scheme
17 allowing the simultaneous integration of internal and external modes on long time
18 runs in a fast and conservative way.
19

21
22
23
24
25
26
27
28
29
30
31

32 Equations were discretized in finite differences on a staggered “C” grid as
33 defined by Arakawa and Lamb (1977). A sigma-coordinate vertical
34 transformation, locally refined near surface and bottom, is used. Attention has
35 been paid to the formulation of the horizontal pressure gradient, and a fourth order
36 scheme (Shechepetkin and McWilliams, 2003) was implemented. The vertical
37 turbulent diffusion of momentum, heat and salt is computed from an algebraic
38 relation (Pacanowsky, 1981) introducing a stratification effect through the local
39 Richardson number. A Laplacian-type horizontal viscosity coefficient is
40 computed from Smagorinsky’s formulation (Smagorinsky, 1963) bounded by
41 lower and upper limits (respectively equal to $1 \text{ m}^2 \cdot \text{s}^{-1}$ and $200 \text{ m}^2 \cdot \text{s}^{-1}$). Particular
42 attention was paid here to the sharpness of density fronts using a TVD scheme
43 (Harten, 1983) for heat and salt advection in combination with a second order
44 Quick scheme (Leonard, 1979) for momentum advection.

2.2.1 Model configurations

The initial coarse model configuration (hereafter called the NORMED configuration) computes the Northern Basin circulation with a 1.2 km horizontal grid and 30 vertical sigma layers. Its southern open boundary is located at 39.5°N between Spanish and Italian coasts. A finer grid model using a 400 m mesh size is then embedded in NORMED over the Gulf of Lions domain (**Fig. 1**). Details of this high resolution model configuration are described in **Table 2**.

2.2.2 Initial and boundary conditions

The MFS (Mediterranean Forecasting System) global Mediterranean model using data assimilation (Pinardi et al., 2003) provides initial state and boundary conditions for the NORMED model. The MFS model computes the whole Mediterranean Sea with a 3 km horizontal grid and 72 vertical levels with a 24 h time step. The output fields (temperature, salinity, current and sea surface elevation) are linearly interpolated on the NORMED grid. At the open sea boundary, the sea surface elevation is prescribed with a contribution of the prognostic interior solution. This method is known as the Flow Relaxation Scheme (FRS) proposed by Martinsen and Engedahl (1987). An upstream condition is applied to temperature and salinity scalar fluxes. This implies that the external fields are advected into the smaller domain during inflow situations only. Moreover, in a band of ten grid steps, temperature and salinity are relaxed toward the values obtained from the coarser grid model using a constant coefficient, thus introducing a time relaxation scale of approximately two days. Furthermore, on the same layer, a sponge condition using an exponential increase in momentum viscosity coefficients is applied along the open boundary in order to dampen potential numerical instabilities generated by the FRS. The same boundary conditions are applied to the eastern and southern boundaries of the nested GoL

1
2
3
4 model located at 7.27°E and 41.66°N, respectively. This zoom configuration was
5
6 run over the two ECOLOPHY cruises after a 1-month spin-up modeling exercise.
7
8 Potential difficulties in modeling may arise, due to the fact that the Northwestern
9
10 Mediterranean Sea is highly sensitive to ocean-atmosphere exchanges. The use of
11
12 a high-resolution atmospheric model is therefore essential, in order to take into
13
14 account the orography effects on the wind fields and to depict as precisely as
15
16 possible the strong variability of atmospheric fluxes in this area. Furthermore,
17
18 land-sea temperature discontinuity which induces thermal breezes must be
19
20 accurately modeled. For the present investigation, a regional atmospheric forcing
21
22 computed with the MM5 (5th generation PSU/NCAR mesoscale model)
23
24 atmospheric model is used. This model provides three hourly radiative solar and
25
26 long-wave fluxes, air temperature at the sea surface, humidity at 2 m and wind at
27
28 10 m heights on a 3 km grid. The wind stress, together with the latent and sensible
29
30 heat fluxes, are calculated from the atmospheric parameters and from the modeled
31
32 Sea Surface Temperature (SST), using the iterative bulk formulae based on the
33
34 Monin-Obukhov similarity theory; see Geernaert (1990) for details.

36
37
38
39

40 **3 Results and discussion**

41 **3.1 ADCP moorings**

42 **3.1.1 Mean current and fluctuations**

43
44
45
46
47
48 Statistics are computed from current measurements obtained from M1 and M2
49
50 ADCP moorings over the whole recording period, and from positions of drogued
51
52 Surdrift buoys that were neither trawled nor grounded and still in the GoL area
53
54 (defined by a box comprised between 3–6°E and 41.5–43.5°N). The inertial
55
56 frequency band (ca. 17.5 hr), which is the major high frequency signal, is beyond
57
58
59
60
61
62
63
64
65

1
2
3
4 the scope of this present study. Thereafter, time series were thus filtered with a
5
6 low-pass Lanczos filter with a cut-off period of 40 hr.
7

8 The current ADCP measurements at 50 m depth, given in figure 2, show high
9
10 variability. Ship-borne ADCP measurements along across-slope sections show
11
12 that the NC core is characterized by velocities greater than 30 cm.s^{-1} at depths of
13
14 50 m in the summer (**Fig. 13**). It is also now well-established that the NC
15
16 velocities are at their minimum during this season (Albérola et al., 1995). So, in
17
18 keeping with this minimum criterion, figure 2a) which represents current
19
20 measured in the main NC direction (SW-NE), shows that the core of the NC
21
22 rarely reached the ADCP mooring, except in the winter, when the NC is known to
23
24 be narrower and stronger. Velocities in the SW-NE direction remain negative,
25
26 indicating that ADCP moorings are influenced by the NC edge. This is
27
28 corroborated by the time-averaged mooring current measurements (**Fig. 3a**) which
29
30 show that mean currents are mainly oriented southwestward. In the upper levels
31
32 (50 and 100 m depths), the direction of the time-averaged currents are west-
33
34 southwestward, following the mean bathymetry, while the time-averaged currents
35
36 follow local bathymetry closer to the bottom. The relatively large eccentricities of
37
38 the variance ellipses (**Fig. 3b**), ranging from 0.68 to 0.84 for M1 and from 0.75 to
39
40 0.88 for M2, indicate that the current fluctuations are mainly rectilinear. When
41
42 depth increases, the eccentricity of the variance ellipses also increases. This
43
44 indicates that in the upper levels (depths of 50-100 m), fluctuations are more
45
46 isotropic than at near-bottom levels, where current oscillations are strongly
47
48 constrained in direction by the local bathymetry.
49
50
51
52
53
54
55

56 As reported in **Table 1**, mean Surdrift buoy velocities range from 8 to 24 cm.s^{-1}
57
58 during the first three legs (EXP-1) and from 14.9 to 32 cm.s^{-1} during legs 4 and 5
59
60 (EXP-2). Hence, we note an increase in NC velocities between EXP-1 (late
61
62
63
64
65

1
2
3
4 spring) and EXP-2 (late autumn and early winter). Moreover, no significant mean
5
6 velocity differences are observed from these Surdrift buoy trajectories at depths
7
8 between 50 and 75 m. Velocities measured by ADCP moorings (at points M1 and
9
10 M2) show that the mean current decreased from the surface to the bottom. For the
11
12 M2 location, the mean velocity at 50 m is ca. 9.2 cm.s^{-1} , and then decreases to 6.7
13
14 and 6.4 cm.s^{-1} at 100 and 150 m depths, respectively. For the M1 location, the
15
16 same tendency is observed with a decrease in the mean velocity from 12.1 cm.s^{-1}
17
18 at 50 m to 4.6 cm.s^{-1} at 350 m.
19
20
21
22

23 **3.1.2 Mesoscale variability of the NC**

24
25 The goal of this section is to define the mesoscale variability of the NC and to
26
27 assess its origin. As an estimate of the mesoscale activity, the centered variance of
28
29 the current is defined by $(\sigma_u^2 + \sigma_v^2)/2$ over a 10-day period (**Fig. 4a** M2; and **Fig 4b**
30
31 M1) from ADCP mooring current measurements (Taupier-Letage and Millot,
32
33 1986). From these figures, it can be observed that mesoscale activity weakens
34
35 with depth from 50 m to the bottom. These figures exhibit three interesting
36
37 periods: (i) from October to December, (ii) from January to February and (iii)
38
39 from April to May.
40
41
42

43
44 (i) From October to December the NC variability increases when the NC has
45
46 been depicted as relatively wide and shallow (Albérola et al., 1995). This
47
48 variability increase is especially observed at M2, at 50 m depth. Considering that
49
50 this increase is not observed at M1 and that it is observed mostly at 50 m depth, it
51
52 could be related to wind effects affecting only the upper part of the NC. Indeed,
53
54 below, the NC flows independently of wind conditions, which could explain the
55
56 similar variability at M1 and M2 sites. Wind velocity (**Fig 5a and b**) reveals the
57
58 presence of southeastern winds in October and mid-November, which were
59
60 potentially able to displace the NC northward shorewards. Moreover, in figure **5c**,
61
62
63
64
65

1
2
3
4 high wind variance values can be seen during November. In December, when the
5
6 NC becomes deep and narrow with maximal current velocities (Albérola et al.,
7
8 1995), mesoscale activity rapidly increased at all depths. The highest variance
9
10 values are reached at the beginning of February.

11
12 (ii) The variability observed during January-February, both at M1 and M2,
13
14 from 50 m down to 400 m depth, might indicate that the NC moves onshore,
15
16 affecting entirely both M1 and M2. Moreover, this increase in the mesoscale
17
18 variability is also associated with strong southeastern winds in January, and with
19
20 high wind variance values. Then, in February the variance signal suddenly
21
22 decreases until the beginning of March, a period when the current is known to
23
24 weaken, becomes wider and shallower and is moved away from the coast
25
26 (Albérola et al., 1995). These features are remarkably consistent with those
27
28 previously obtained during PRIMO-0 (Albérola et al., 1995), PROGLI-2 and
29
30 PROS-6 (Sammari et al., 1995) and DYOME (Taupier-Letage and Millot, 1986)
31
32 experiments.
33
34
35
36
37

38 (iii) Finally, April and May show two main peaks. Compared to winter peaks,
39
40 those occurring during April-May are more barotropic, in the sense that similar
41
42 variability is recorded from 50 down to 300 and 400 m depth during May and
43
44 April, respectively. This observation is particularly true at M1 location, possibly
45
46 indicates that the NC is moved offshore and deepens. Hence, mesoscale current
47
48 activity is well correlated with seasonal variability of the NC. Nevertheless, wind
49
50 might also have a significant effect.
51
52
53
54

55 **3.1.3 Spectral analysis**

56
57 Kinetic energy spectra are computed from 1 hr integration time series of
58
59 currents collected with two ADCP moorings (named M1 and M2), using
60
61 frequency-averaging (Mercier, 1991). The Number of averaged frequency is 5 or
62
63

1
2
3
4 3 indicated by the confidence interval plotted in the top of figures 6. Currents
5 were previously filtered out from the original time series with a low-pass Lanczos
6 filter with a cut-off period of 40 hr.
7
8
9

10 Kinetic energy spectra computed from depth-averaged current measured by the
11 two ADCP moorings are shown on figure 6a. These spectra correspond almost to
12 the barotropic current oscillations. Energy peaks around 5.5-, 10- to 15- and 30-
13 day periods are observed for M2 and at 3.8-, 5- to 6.5-, 9-, 11.6- and 20- to 30-day
14 periods for M1. Spectra are also computed at several depths to investigate vertical
15 oscillation structure. These spectra reveal that the energy is higher in upper levels
16 and decrease with depth. M1 (Fig. 6c) and M2 (Fig. 6b) peaks are rather similar,
17 and two main frequency bands can be discerned: one from 3- to 5.3-day and a
18 second from 9- to 15-day periods. Other peaks are also visible at periods equal to
19 or greater than 21 days. These kinetic energy spectra seem to be relatively
20 coherent in the vertical direction for M2, whereas for the M1 the behavior of
21 variability is slightly different at the surface compared to deeper levels.
22
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37

38 Kinetic energy spectra computed from depth-averaged modeled current at M1
39 and M2 are plotted on figure 7. Comparison with spectra computed from
40 measured currents shows that energy of fluctuations is in the same range.
41 Moreover, two main bands of fluctuation at mesoscale can also be distinguished: a
42 first one from 2.7 to 7 day and a second one between 9 and 13 days.
43
44
45
46
47
48
49
50
51

52 Spectral analysis gives the orientations of the current ellipses and the principal
53 axes at the energy peaks (Mercier, 1991). In figure 8, the only current ellipses
54 corresponding to periods close to 11.6, 5.4 to 4.7 and 3.8 days for the M1
55 mooring, and 13.3, 5.3 and 3.3 to 3.7 days for M2, are plotted. These variance
56 ellipses clearly show that current oscillations at 11 and 13 days are mainly
57
58
59
60
61
62
63
64
65

1
2
3
4 oriented in the direction of the mean current, i.e. southwestward (**Fig. 8a and 8b**).
5
6 At 5.3 days, for M2 (**Fig. 8d**) ellipses are also in the along-slope direction in the
7
8 lower levels (100 and 150 m depths), but tend to be slightly in the cross-slope
9
10 direction at 50 m depth. Fluctuations between 4.7- and 5.4-day periods, for M1,
11
12 are oriented cross-slope (**Fig. 8c**). At the 3.8- to 3.4-day period, current
13
14 oscillations are in the cross-slope direction in the upper levels with low
15
16 eccentricities (0.63-0.68 at 100 m depth). These results show similarities for peaks
17
18 from 3.3 to 5.4 days for both M1 and M2 locations which reinforce the conclusion
19
20 done on spectral analysis that these peaks could all be considered as a single
21
22 fluctuation band with similar characteristics. Fluctuations measured at M1 and M2
23
24 at periods ranging between 20 and 30 days (not shown), are strongly constrained
25
26 in the along-slope direction with quite large ellipse eccentricities (between 0.95-
27
28 0.99 for all levels). The most isotropic oscillations are measured at M1, where
29
30 eccentricities reach 0.44 and 0.66 at periods of 6.3 and 8.9 days, respectively (not
31
32 shown).
33
34
35
36
37

38 Hence, fluctuations measured at the 9-15 day-period band follow the local
39
40 bathymetry at all depth. Fluctuation at the 3.3-5.4 days band tend to be oriented
41
42 cross-slope in the upper layer (<100 m), turning along-bathymetry closer to the
43
44 bottom. At M1 location, fluctuations are rather isotropic closer to the bottom and
45
46 between the two major frequency bands. These behaviors can be due to the U-
47
48 shape of the canyon head's topography at the M1 site location. These results are in
49
50 accordance with previous measurements collected off the city of Nice by Sammari
51
52 et al. (1995) who showed that from May to December, the 10- to 20-day band was
53
54 recorded only in along-slope direction, whereas the 3- to 6-day period mainly
55
56 appeared to be in the cross-slope direction. Nevertheless, during winter, the 10- to
57
58 20-day fluctuation band presented similar amplitudes in the along-shore and
59
60
61
62
63
64
65

1
2
3
4 cross-shore components, suggesting a relationship to large mesoscale meanders.
5
6 In both winter and spring, records from Albérola et al. (1995), the 3- to 6-day
7
8 band fluctuations were also associated with meandering currents. Current
9
10 measurements done over the continental slope of the GoL showed fluctuations at
11
12 lower periods compared with those off Nice. Hence, Durrieu de Madron et al.
13
14 (1999) found two fluctuation periods: one at 2 to 5 days and a second one at 7 to
15
16 10 days. These were associated with both along- and cross-slope components and
17
18 were clearly associated with NC mesoscale meandering. Fluctuations of periods
19
20 longer than 10 days occurred mostly in the along-slope direction.
21
22
23
24

25 **3.2 Measurements along sections**

26 **3.2.1 Hydrological features**

27
28
29 In this section, we examine density fields collected during EXP-1 through the
30
31 three sections: T1, T2 and T3 (classified from east to west, from the eastern
32
33 entrance of the gulf; see **Fig. 1**). Figure 9 shows potential temperature (θ), salinity
34
35 and density distributions along sections, computed from vertical CTD profiles
36
37 performed from May 29 to June 2, 2005. These sections evidenced well known
38
39 water masses (Millot, 1990; Durrieu de Madron et al., 1990; Durrieu de Madron,
40
41 1994; Lapouyade and Durrieu de Madron, 2001): the water of Atlantic origin
42
43 (AW) evidenced by relatively warm and fresh waters ($\theta > 13.3^\circ\text{C}$ and $S < 38.45$)
44
45 extending near the shelf-break, over the upper continental slope, from surface to
46
47 approximately 300 m depth and the Levantine Intermediate Water (LIW) below,
48
49 characterized by a relative maximum of θ and S between 300 and 500 m depth
50
51 close to the slope. These water masses are also visible on θ - S diagram (**Fig. 10**).
52
53
54 Along the T1 section (**Fig. 9a**), the AW vein is located to the north of 42.9°N
55
56 down to a depth of about 300 m. The isopycnals associated to the lower limit of
57
58
59
60
61
62
63
64
65

1
2
3
4 AW (on the order of 29) show a strong slope in this location. In the T2 and T3
5
6 sections (**Fig. 9b and 9c**), the AW is visible to the north of 43.00°N and 42.9°N,
7
8 respectively. On the three sections, a low temperature cell is observed with
9
10 $\theta < 13.2^\circ\text{C}$, at ca. 150 m depth. This cold water lens might be formed by cooling of
11
12 the AW during winter, occurring upstream in the Ligurian Sea, and then advected
13
14 below the surface. This water mass referred as the Winter Intermediate Water
15
16 (WIW) by Millot (1999) is depicted as cold water in combination with low
17
18 salinity values. In the southern part of the T1 and T3 transects (between 42.5 and
19
20 42.7°N), the local increase in the slope of isotherms and isohalines need to
21
22 be interpreted with care. It may be a consequence of the radius of influence (ca. 15
23
24 km) used in the interpolation procedure, which might be too small comparing to
25
26 the CTD spacing at this location.
27
28
29
30
31
32

33
34 Figure 11 displays sections of 400m-grid resolution modeled density averaged
35
36 from May 30 to June 2, 2005. The comparison of these results with the
37
38 measurements collected during EXP-1 shows resemblances. Along section T1, the
39
40 shape and depth of the 29 isopycnals are similar, but the density slope has a more
41
42 southerly location in the model results (**Fig. 11a**) than in the hydrological
43
44 measurements (**Fig. 9a**). The shift in the main isopycnal slope is also observed in
45
46 section T3 (**Fig. 11c**). These shifts in the 29 isopycnal slopes are about 11 km for
47
48 T1 and 20 km for T3. Moreover, near the shelf-break, modeled density is slightly
49
50 higher than in the measurements. That is, isopycnals are deeper in the model
51
52 results. All along section T2 (**Fig. 11b**), the density slope remains weak in the
53
54 model outputs as well as in data.
55
56
57
58

59 Horizontal density fields measured at 50 m depth are shown in figure **12a**.
60
61 Comparison between measurements and the high-resolution model results
62
63
64
65

1
2
3
4 averaged during the ECOLOPHY-1 period (**Fig. 12b**) reveals that the density
5
6 fields are in the same range. Moreover the convex shape of the density front is in
7
8 accordance with observations. Therefore, there is important difference along
9
10 section T1 and T3. Indeed, considering the 28.8 isopycnal, the density front is
11
12 fairly reproduced offshore. This lack might be due to the large scale forcing and
13
14 initialization fields because it is also present in the MFS large scale modeled
15
16 outputs.
17
18

19
20 This discrepancy is also visible comparing modeled and measured velocities at
21
22 50 m depth along the ship track (**Fig. 12c** and **12d**). The NC, due to this density
23
24 front, shows a more southerly position and a lower intensity than in observations.
25
26 Along T1, a secondary vein of current, which is not observed from data field, is
27
28 also modeled. Considering the modeled density field (**Fig. 11a**), this secondary
29
30 vein would correspond to an adjustment of the isopycnal slope at 42°65'N. This
31
32 feature is due to a non-realistic off-shore re-circulation eddy which merges with
33
34 the main core current between T1 and T3. Moreover, modeled NC along section
35
36 T3 is not correctly oriented, indicating that current meanders are not correctly
37
38 simulated in this area.
39
40
41
42
43

44 **3.2.2 Velocity features**

45
46 The geostrophic currents across transects are plotted in the top of figure **13**.
47
48 These currents are computed from density profiles along sections T1 and T3 with
49
50 a reference level at the bottom depth, limited at 500 m depth. In the middle of
51
52 figure **13**, currents measured perpendicular to sections by hull-mounted ADCP are
53
54 also shown. Comparison of the computed geostrophic component of the current
55
56 with the observed one shows that the NC location and intensity are highly similar.
57
58 In section T1 (**Fig. 13a**), the NC reached 45 cm.s⁻¹ at 30 m depth and its width is
59
60 about 30 km. The width of the computed geostrophic current is about 35 km. The
61
62
63
64
65

1
2
3
4 maximum geostrophic current computed across section T3 (**Fig. 13b**) is greater
5
6 than 45 cm.s^{-1} on the surface. The measured current is of the same order but shows
7
8 the highest intensity at ca. 50 m depth. From the hull ADCP measurements, we
9
10 observe that the NC moves about 10 km between May 30 and June 1, 2005 along
11
12 section T1, and between May 29 and June 2, 2005 along section T3. This
13
14 temporal variability is not detected by CTD measurements because profiles
15
16 collected during this 4-day period have been interpolated to plot these sections.
17
18 Moreover, the CTD spacing that is larger than the internal radius of deformation
19
20 also lead to a smoothing of the density field and geostrophic velocities. This could
21
22 explain the wider horizontal extent of the computed geostrophic current.
23
24 Nevertheless, since the computed density currents and measurements are quite
25
26 similar, it is clear that the NC is mainly in geostrophic equilibrium. The NC
27
28 velocity and its width give a Rossby number ($R_0=U/fL$) ranging between 0.11 and
29
30 0.16. These R_0 values are close to those previously reported in the literature (0.1 in
31
32 Sammari et al. (1995) and 0.16 in Flexas et al. (2002). A secondary geostrophic
33
34 current is also computed in section T3 at ca. 42.62°N . This current is an artifact
35
36 due to the interpolation method used to compute density fields (see previous
37
38 section). Transport of the NC across the three sections, computed from
39
40 geostrophic velocities down to a depth of 500 m, is 1.41, 0.92 and 1.18 Sv,
41
42 respectively.
43
44
45
46
47
48
49
50
51

52 Velocity features measured with hull-mounted ADCP perpendicular to section
53
54 T1 and T3 are also compared to model outputs. Hence, modeled currents were
55
56 spatially and temporally interpolated at the measured points. Comparisons, shown
57
58 on figure **13**, indicate that the modeled NC vein is located 15 km to the south
59
60 compared to the actual measurements. This is in agreement with density fields
61
62
63
64
65

1
2
3
4 (section 3.2.1). This flaw of the model simulation might be due to bathymetric
5
6 effect through horizontal turbulence and vertical pressure gradient computation,
7
8 which are not correctly evaluated in the model. The NC is simulated with realistic
9
10 width and intensity despite the fact that the latter is slightly underestimated.
11
12 Another difference is that Vessel-mounted ADCP profile along T1 presents high
13
14 variability in the first 20 m of the water column, whereas model output shows an
15
16 absence of velocity. This is due to an over-estimation of the wind effect on
17
18 surface layer. Nevertheless, a mixed surface layer of about 15 m depth is
19
20 measured. Below, NC's asymmetrical depth pattern, which has been attributed to
21
22 wind-induced surface circulation (Dufau-Julliand et al., 2004) is reproduced by
23
24 the model.
25
26
27
28
29

30 ***3.3 Drogued-buoy trajectories***

31
32 Drifter trajectories provide information on the current at 50 and 75 m depths
33
34 over the slope of the GoL and in the shelf. Five different deployments were
35
36 performed (**Table 1**): three legs during EXP-1 (at the end of spring 2005) and two
37
38 during EXP-2 (at the end of autumn 2005). It is clear on figure **14** that buoys tend
39
40 to flow southwestward along the continental slope. Nevertheless, it is possible to
41
42 distinguish two kinds of trajectories: a first one flowing over the upper slope up to
43
44 the 1000 m isobath as during legs 2 and 4 (**Fig. 14a** and **14c**), and a second one
45
46 flowing over the lower slope between the 1000 and 2000 m isobaths (legs 3 and 5
47
48 on figures **14b** and **14d**).
49
50
51
52
53
54

55 Here, we will describe the trajectories in the eastern part of the gulf,
56
57 corresponding to the ECOLOPHY field campaign zone. Trajectories of buoys
58
59 launched during the second deployment (**Fig. 14a bis**) show a number of small-
60
61
62
63
64
65

1
2
3
4 scale anticyclonic eddies, with a scale of a few kilometers. This circulation is due
5
6 to the creation of vorticity behind the Cape Sicié (located on figure 1). During the
7
8 third buoy deployment, trajectories are observed rather homogeneous (**Fig. 14b**).
9
10 They first flow southwestward and then are oriented northwestward before being
11
12 guided by the slope. This kind of trajectory is characteristic of an upwelling
13
14 circulation, which is known to occur south of Cape Sicié (André et al. 2005).
15
16 Indeed, there is a storm with strong northwesterly winds (up to 15 m.s^{-1} on July 1,
17
18 **Fig. 15a**) from June 30 to July 2, 2005. This type of wind produces an offshore
19
20 current in upper water levels compensated by an upwelling of waters from below.
21
22 Such upwellings can persist during several days after the wind stops, explaining
23
24 the southwestward circulation up to July 4. Then the wind weakens and changes
25
26 to the east leading buoys toward the northwest. In figure **14b**, the '3b' buoy
27
28 trajectory shows an intrusion of slope water onto the shelf at its eastern entrance
29
30 in the Cassis Canyon (**Fig. 1**). Indeed, when stratification is strong enough with a
31
32 shallow pycnocline, as it the case here, part of the NC can follow the eastern coast
33
34 of the gulf and intrudes into the shelf (Echevin et al., 2003). Furthermore, this
35
36 phenomenon is reinforced in the case of weak northeasterly winds (Petrenko et al.,
37
38 2005; Petrenko, 2003). This buoy is then advected eastward by a coastal current
39
40 generated during the upwelling relaxation. During the fifth buoy deployment in
41
42 late autumn (**Fig. 14d**), trajectories of the four Surdrifts are identical on the
43
44 eastern part of the gulf as far as $5^{\circ}17'E$ where the buoy '5a' moves toward the
45
46 upper slope, whereas the other ones follow the lower slope. Northeasterly winds
47
48 blow over the extreme east of the gulf, between December 9 and 10, 2005 (**Fig**
49
50 **15b**). The corresponding model outputs clearly show a northward current at about
51
52 $5,15^{\circ}E$. Hence the buoy '5a' is advected toward the upper slope and then is
53
54 advected westward by a secondary flow visible at $43^{\circ}N$.
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4
5
6 In this section, we describe the buoy trajectories in the whole GoL domain.
7
8 Figure **14a** clearly shows anticyclonic eddy trajectories over the shelf-break for
9
10 buoys named: ‘2b’, ‘2d’, ‘2f’ and ‘2g’. Centered at 4°20’E and at 3°50’E, these
11
12 mesoscale eddies have a diameter of a few dozen kilometers. Ertel Potential
13
14 Vorticity (EPV) anomaly is computed as:
15

$$16 \quad \delta(EPV) = \frac{N^2}{g}(f + \zeta) - \frac{N_0^2 f_0}{g},$$

17
18 where f is the coriolis frequency, ζ the relative vorticity, g the gravity and N the
19
20 Brunt-Vaisala frequency. EPV is conserved for non-dissipative and adiabatic
21
22 motion, making this a useful tool for following water particles (Buongiorno
23
24 Nardelli et al., 2001). On June 20, the ‘2g’ buoy left the NC at 4°E. This
25
26 northward motion is clearly noticeable in the center part of the GoL’s slope (4°E –
27
28 42°42’N) on the modeled EPV and velocity fields at 50 m depth (indicated by
29
30 letter **F** on **Fig. 16a**). This motion is associated with NC filaments which drive
31
32 slope water northward. A few days later, this buoy is trapped by a weak
33
34 countercurrent, which drives water eastward. Indeed, on figure **17**, an eastward
35
36 current with velocities lower than 10 cm.s⁻¹ is observed over the shelf-break in the
37
38 whole water column. On June 29 (**Fig. 16b**), an anticyclonic eddy is formed in the
39
40 western part of the continental slope at about 3°50’E – 42°30’N (indicated by
41
42 letter **E**). EPV field shows that a part of the NC is driven westward by this
43
44 mesoscale feature while the main current is oriented southward. Furthermore, the
45
46 field computed on June 29 (**Fig. 16b**) reveals a NC meander which is also
47
48 described by the ‘2g’ buoy. Hence, these EPV maps show eddies and meanders
49
50 which drive drifter buoys. Therefore, the simulation realistically reproduces these
51
52 mesoscale features of the current.
53
54
55
56
57
58
59
60
61
62

1
2
3
4 During the fifth deployment (**Fig. 14d**), the ‘5a’ buoy flows along the upper
5
6 continental slope between the 200 and 500 m isobaths as far as the 4°10’E
7
8 longitude, where it penetrates into the shelf. This kind of circulation was detected
9
10 during heterogeneous winds due to adjacent northern (Mistral) and a northwestern
11
12 (Tramontane) wind situation inducing a strong wind curl, which involves a
13
14 cyclonic circulation in the western part of the GoL and an anticyclonic circulation
15
16 in the northern part, driving water northward (Estournel et al., 2003). These
17
18 heterogeneous winds take place from December 16 to 20, 2005 (**Fig 15c**).
19
20 Although gyres are not as obviously observed as in the theoretical simulations
21
22 performed by Estournel et al. (2003), a northwestward current is visible in the
23
24 center of the gulf (at ca. 4°15’E). Then, a Tramontane regime occurs, which
25
26 induces cyclonic circulation in the western part of the gulf. Thus, drifter ‘5a’
27
28 flows along the GoL coasts, and continues towards the Catalan continental shelf.
29
30 Behind Cape Creus there is an anticyclonic eddy, apparent in both figure **16b** and
31
32 figure **14d**. This feature is due to the creation of vorticity behind the Cape similar
33
34 to that observed past Cape Sicié.
35
36
37
38
39

40 **5 Conclusions**

41
42 The one-year data set collected over the upper continental slope of the Gulf of
43
44 Lions during the ECOLOPHY experiment allows us to complement the
45
46 description of the Northern Current mesoscale variability. A high-resolution
47
48 hydrodynamic model (400 m grid size) is used to better understand NC mesoscale
49
50 features, such as meanders, anticyclonic eddies and filaments forming over the
51
52 shelf-break as revealed by Surdrift buoy trajectories.
53
54
55

56
57 Current measurements provided by ADCP moorings clearly show the
58
59 southwestward drift of the NC along the slope. Although the current core rarely
60
61 reaches the moorings themselves, they are influenced by the NC edge. The current
62
63
64
65

1
2
3
4 fluctuations near the surface and at mid-depth are principally oriented along the
5
6 main slope direction. Near-bottom current fluctuations are strongly constrained by
7
8 the local bathymetry.
9

10
11 The mesoscale activity of the NC displays an annual maximum in winter for all
12
13 depths, decreasing toward the bottom, in agreement with previous observations.
14
15 This maximum of current variance is correlated with maximum NC flux. A
16
17 secondary maximum occurs in autumn at 50 m depth, associated with strong
18
19 southeasterly gusts. Spectral analyses reveal current oscillations at several
20
21 frequencies ranging between 30 and 3 days. Previous studies off Nice established
22
23 that 2 frequency bands can be distinguished: a first one at 10 to 20 days
24
25 (corresponding to 7 to 10 days over the GoL's slope) and a second one at 3 to 6
26
27 days (2 to 5 days); both of them being associated with Northern Current
28
29 meandering. Flexas et al. (2002) also found two bands of mesoscale activity
30
31 centered at 7 and 3.5 days, off Marseilles. The present study corroborates previous
32
33 observations. Indeed, two main frequency bands are observed: a first from 2.7 to 7
34
35 day and a second between 9 and 13 days. Current ellipses show that current
36
37 oscillations at periods longer than 10 days are mainly oriented in the direction of
38
39 the mean current. At shorter periods, in the 6.3- to 8.9-day period-band,
40
41 fluctuations prove to be mainly isotropic. In the 3.3- to 5.4-day period-band,
42
43 fluctuations are cross-slope, at least in the upper levels. Closer to the seafloor,
44
45 these current fluctuations are often directed along the local bathymetry. These
46
47 low-period bands were previously associated with NC mesoscale meandering.
48
49
50
51
52

53
54 Hydrological data allows us to distinguish the different water masses present in
55
56 the first 500 m as the AW at surface (up to 300 m) and WIW at subsurface (at
57
58 about 150 m depth). The density gradient between AW and open sea water is the
59
60 major driving mechanism of the Northern Current, which remains in quasi-
61
62
63
64
65

1
2
3
4 geostrophic equilibrium. Comparisons of *in situ* density and current data with a
5
6 high-resolution model (400 m horizontal grid) show the overall ability of the
7
8 model to reproduce the major NC characteristics. However, some differences are
9
10 detected concerning the position of the density front, and of the NC which appears
11
12 to be roughly located 15 km south from actual measurements.
13
14

15 The combined analyses of drifter trajectories and modeling results revealed
16
17 several mesoscale processes, such as:
18

- 19
20 • Wind-induced upwelling off Cape Sicié which drives the NC southwestward,
21
22 generally followed by an intrusion of slope water onto the eastern part of the
23
24 shelf during relaxation, as previously evidenced by Millot and Wald (1980);
25
26
- 27 • Formation of anticyclonic mesoscale NC eddies and filaments over the upper
28
29 continental shelf, due to current instabilities. Slope water is then driven
30
31 northward over the shelf-break, before being advected by an eastward
32
33 countercurrent and finally comes back to the main current. These features were
34
35 already observed on Sea Surface Temperature satellite images by Flexas et al.
36
37 (2002);
38
39
- 40 • A northward current, in the center part of the shelf, due to the simultaneous
41
42 occurrence of Mistral and Tramontane winds, inducing cyclonic and
43
44 anticyclonic circulations, respectively, in the western and in the eastern part of
45
46 the gulf, as already pointed out by Estournel et al. (2003).
47
48
49
50
51

52 This first interpretation of the ECOLOPHY measurements using model results
53
54 showed that mesoscale current features over the shelf-break are also modeled.
55
56 Nevertheless, numerical modeling need to be validated, especially concerning
57
58 initial vorticity and separation from the coast in Cape Sicié site to better
59
60 understand the discrepancies observed in the modeled trajectory on this slope
61
62
63
64
65

1
2
3
4 current. Then, the origin of the NC mesoscale variability over the continental
5 slope, which has been related to barotropic/baroclinic instabilities, will be
6 investigate in more detail using this model configuration for different test cases to
7 especially examine effects of the bathymetry and wind forcing. Moreover, the
8 study of the NC mesoscale variability will be completed with recent
9 measurements in order to asses the inter-annual variability of mesoscale activity.

| First Deployment | | | | | | | |
| 1a | 50 m | 05/29/2005 | 42.954 N | 5.730 E | 3/6/2005 | 5 | 13 |
| 1b | 50 m | 05/29/2005 | 42.924 N | 5.816 E | 3/6/2005 | 5 | 15 |
| 1c | 50 m | 05/29/2005 | 42.985 N | 5.898 E | 3/6/2005 | 5 | 8 |
| 1d | 75 m | 05/29/2005 | 42.917 N | 5.814 E | 3/6/2005 | 5 | 24.3 |
| 1e | 50 m | 05/29/2005 | 42.959 N | 5.723 E | 3/6/2005 | 5 | 12.9 |
| Second Deployment | | | | | | | |
| 2a | 50 m | 1/6/2005 | 42.908 N | 5.821 E | 5/8/2005 | 65 | 10.3 |
| 2b | 50 m | 1/6/2005 | 42.957 N | 5.726 E | 1/8/2005 | 61 | 11.7 |
| 2c | 50 m | 1/6/2005 | 42.960 N | 5.721 E | 5/6/2005 | 4 | 11.3 |
| 2d | 50 m | 1/6/2005 | 42.915 N | 5.821 E | 07/19/2905 | 47 | 13 |
| 2e | 75 m | 1/6/2005 | 42.93 N | 5.761 E | 11/6/2005 | 9 | 13.8 |
| 2f | 75 m | 1/6/2005 | 42.896 N | 5.819 E | 4/7/2005 | 33 | 11.3 |
| 2g | 50 m | 1/6/2005 | 42.926 N | 5.767 E | 07/23/2005 | 52 | 13 |
| Third Deployment | | | | | | | |
| 3a | 50 m | 3/7/2005 | 42.958 N | 5.925 E | 08/14/2005 | 42 | 10 |
| 3b | 50 m | 3/7/2005 | 42.95 N | 5.915 E | 08/15/2005 | 43 | 8.7 |
| 3c | 50 m | 3/7/2005 | 42.933 N | 5.917 E | 08/19/2005 | 47 | 12.3 |
| 3d | 75 m | 3/7/2005 | 42.914 N | 5.92 E | 08/20/2005 | 48 | 9 |
| 3e | 50 m | 3/7/2005 | 42.998 N | 5.913 E | 7/7/2005 | 4 | 13.4 |
| Fourth Deployment | | | | | | | |
| 4a | 50 m | 1/12/2005 | 42.907 N | 5.806 E | 01/18/2006 | 42 | 22.4 |
| 4b | 50 m | 1/12/2005 | 42.973 N | 5.730 E | 12/15/2005 | 14 | 31.5 |
| 4c | 50 m | 1/12/2005 | 42.974 N | 5.720 E | 12/23/2005 | 22 | 30.2 |
| 4d | 50 m | 1/12/2005 | 42.911 N | 5.810 E | 11/12/2005 | 11 | 29.2 |
| Fifth Deployment | | | | | | | |
| 5a | 50 m | 8/12/2005 | 42.908 N | 5.821 E | 01/30/2006 | 52 | 14.9 |
| 5b | 50 m | 8/12/2005 | 42.957 N | 5.726 E | 01/31/2006 | 53 | 14.9 |
| 5c | 50 m | 8/12/2005 | 42.908 N | 5.821 E | 01/19/2006 | 41 | 19.6 |
| 5d | 50 m | 8/12/2005 | 42.957 N | 5.726 E | 01/19/2006 | 41 | 19.6 |

Table 2[Click here to download Table: Table1.xls](#)

| | | |
|--|-----------------|---------------------------------------|
| Resolution: | Horizontal: | 400 m |
| | Temporal: | 150 s |
| Number of sigma layer: | | 30 |
| Spin-up | | 1 month |
| Forcing: | Meteorological: | MM5 atmospherical model (3 km; 3 h) |
| | Open boundary: | NORMED configuration (1.2 km; 3 h) |
| | River runoff: | Daily Rhone river outflow |
| Vertical viscosity: (Pacanowsky and Philander 1981) | Minimum: | $1.10^{-5} \text{ m}^2.\text{s}^{-1}$ |
| | maximum: | $5.10^{-3} \text{ m}^2.\text{s}^{-1}$ |
| Horizontal viscosity: (Smagorinsky, 1963) | Coefficient | 0.25 |
| | Minimum Value | $1 \text{ m}^2.\text{s}^{-1}$ |
| | Maximum Value | $200 \text{ m}^2.\text{s}^{-1}$ |
| Horizontal diffusivity: | | $1 \text{ m}^2.\text{s}^{-1}$ |
