### Abstract:

The development of ecosystem-based indicators requires the broadening of a view of the community, from fish species to all the species (macrobenthic and fish) correctly captured by a given sampling gear. Many scientific surveys already have such integrated databases. The present note aims to demonstrate that existing databases, herein from dedicated coastal nursery surveys, are actually underexploited. Such databases contain information on non-commercial taxa, which could greatly improve our knowledge on the organisation and functioning of coastal ecosystems. Using two datasets, a "complete" dataset composed of commercial and not-commercial epibenthic trawled species (fish and invertebrate) and a "subset" dataset characterized by commercial and routinely surveyed species (mainly fish and cephalopods), different measures of functional diversity are compared to identify the functional gains of including epibenthic species. The results show that, when included in the analyses, epibenthic taxa provide gains of functional information, associated mainly with the community feeding traits, i.e. organisms composing the primary and secondary consumer levels of the coastal nursery food web. Failure to include some of the primary (zooplanktivores and suspension feeders) and secondary consumers (detritivores–scavengers) in coastal survey analyses may, for instance, hamper our understanding of energy flux between the benthic and water column compartments of these ecosystems. The results also suggest that the exclusion of some taxa associated with these two food web compartments, may lead to the underestimation of the functional redundancy in coastal ecosystems.

**Keywords:** Bay of Biscay; Beam trawl; Coastal surveys; Fish community; Functional diversity; Nursery grounds

## 1 **Introduction**

2           Recent integrated approaches, such as the Ecosystem Approach to Management, calls  
3 for sustainable and ecosystem-based indicators, that lead towards an understanding of how an  
4 ecosystem functions (Garcia and Cochrane 2005). These indicators require us to broaden our  
5 view of the studied communities, to include commercial as well as non-commercial species  
6 and fish as well as other taxa (e.g. molluscs, echinoderms). In certain ecosystems, such as the  
7 coastal system, indicators integrating both the structural (i.e. species composition) and  
8 functional attributes of the communities are increasingly recognized as useful tools to assess  
9 changes in these ecosystems (Costanza and Mageau 1999; Elliott and Quintino 2007; and  
10 Brind'Amour and Lobry (submitted)).

11           However, development of such ecosystem-based indicators require modification of the  
12 actual fishery surveys, in order to have community-extended program of data collection or, as  
13 in many bottom trawl fishery surveys, an enhanced use of the available databases. In many  
14 beam trawl surveys, such as the IBTS (International Beam Trawl Surveys), or coastal nursery-  
15 dedicated surveys, these data already exist. Beam trawls are very effective in sampling vagile  
16 as well as epibenthic macrofauna and the latter may represent a large proportion (density or  
17 biomass) of the catches (Kaiser et al. 1994; Tillin et al. 2006).

18           It is within this context that the present Note aims to demonstrate that existing  
19 databases are underexploited, as they contain information on non-commercial taxa which  
20 could greatly improve our knowledge on the functioning of marine ecosystems. We have  
21 verified this hypothesis using data from coastal nursery surveys, divided in two datasets: a  
22 complete dataset, which included commercial and non-commercial taxa; and a subset dataset,  
23 which was composed of routinely-surveyed commercial taxa (i.e. mainly fish and  
24 cephalopods).

25

## 1 Materials and Methods

### 2 *Study area and sampling surveys*

3         The study was undertaken in the Bay of Vilaine located along the French Atlantic  
4 coast in southern Brittany (Fig. 1). The bay covers a 230 km<sup>2</sup> surface area from the foreshore  
5 to the 20m isobath; it is characterized by an open shallow muddy estuarine area, under the  
6 direct influence of freshwater inflows (Gilliers et al. 2006). Sampling was carried out from  
7 the end of August to the end of October, between 2000 and 2005. Surveys were carried out  
8 using a stratified sampling design, according to depth and sediment types. Depths ranged  
9 from 5 to 35m and, due to the sampling gear used in this study (i.e. beam trawl), the sediment  
10 types ranged from coarse-grained sand and gravel to predominantly fine sand and/or coarse  
11 silt. Sampling was undertaken using a 2.9 m wide and 0.5 m high beam trawl, with a 20-mm  
12 stretched mesh net in the cod-end. A total of 195 hauls over the 6 years of sampling was  
13 conducted, during the study. Each haul was carried out on sites displaying homogeneous  
14 sediment and water depth and lasted 15 min, covering a mean surface of 4500 to 5000 m<sup>2</sup>.

### 15 *Species datasets*

16         All the individuals caught within a haul were identified at the species level (excluding  
17 the genus *Liocarcinus* and the Paguridae). Species were counted and the total biomass, per  
18 haul, was recorded. A total of 127 species was captured over the six-year surveys.  
19 Considering the selectivity of the sampling gear, towards benthic-demersal species, only the  
20 species occurring in more than 5% of the sampling sites and displaying a relative density  $\geq$   
21 5% of the total density were included in the analyses (i.e. 65 species). However, as this work  
22 was focused upon the functional aspects of the community, we selected species for which  
23 sufficient species-specific information was available; thus, finally, a total of 45 species were  
24 selected (Table 1).

1 Estimation of the functional loss of information was assessed, by the comparison of  
2 two datasets. The first dataset included the 45 aforementioned species and was herein defined  
3 as the “complete” dataset. The second dataset was composed of 25 commercial and routinely  
4 surveyed species, during nursery-dedicated cruises; it is defined further as the “subset” dataset  
5 (Table 1).

### 6 *Species functional groups*

7 A functional description of the community was assessed, by categorizing the species  
8 into four functional guilds (Table 2). These guilds (feeding traits, ecological trait, mobility,  
9 and substrate preference) were selected because they are functionally significant, in  
10 structuring the coastal and estuarine nursery communities (Elliott and Dewailly 1995;  
11 Bremner et al. 2003; and Franco et al. 2008). Therefore, a species-traits matrix was compiled  
12 using information gathered mainly from the literature (Elliott and Dewailly 1995; Raya et al.  
13 1999; Laptikhovsky et al. 2002; Tillin et al. 2006; and Franco et al. 2008) and completed  
14 when necessary with the Marine Life Information Network (<http://www.marlin.ac.uk>) and  
15 Fishbase (Froese and Pauly 2006).

### 16 *Data analyses*

17 Since it is not possible (and somewhat undesirable) to assess the functional differences  
18 between communities using a single index of functional diversity, the comparison between  
19 the two datasets was realized using different measures of functional diversity. As each index  
20 has its own limits and advantages, their combination is likely to provide complementary  
21 information regarding the functional aspects of the community. Therefore, the assessment of  
22 the functional diversity was undertaken in three ways: (i) by the computation of a diversity  
23 index (Shannon diversity index) on the species densities, pooled by functional guilds; (ii) by  
24 cluster analyses, undertaken on the species-traits matrix; and (iii) by the computation of the  
25 functional richness index. Shannon diversity was calculated on species densities pooled by

1 functional guilds. It was computed for each year, then averaged over the six-year surveys to  
2 dampen out the annual variability.

3 Cluster analyses were conducted using Gower's dissimilarity coefficient on the  
4 standardized species-traits matrix (Podani and Schmera 2006). The dendrograms were  
5 produced by hierarchical clustering, using the Unweight Pair Group Method, with the  
6 Arithmetic Mean (UPGMA) method. The number of clusters was identified using the  
7 Calinski-Harabasz criterion, a pseudo  $F$  (ANOVA) statistic which computes the sum of  
8 squared errors (distances) between the  $k^{\text{th}}$  cluster and the other  $k - 1$  clusters; this is compared  
9 then to the internal sum of the squared errors, for the  $k$  clusters, i.e. taking their individual  
10 squared error terms and summing them (Calinski and Harabasz 1974; Milligan and Cooper  
11 1985).

12 The index of functional richness ( $FRic$ ), suggested recently by Villéger et al. (2008),  
13 was used to estimate and compare the volume occupied by the species, in the trait space for  
14 the two datasets. That index is computed following Cornwell et al. (2006); it estimates the  
15 convex hull volume (i.e. the smallest convex set, enclosing the points) using the Quickhull  
16 algorithm. The algorithm first identifies, then links the most extreme points (here, the species)  
17 and computes the volume inside. As this index is calculated from the species-traits matrix, it  
18 is influenced by the identity of the species and, more particularly, by the most dissimilar  
19 species in terms of functional traits (Villéger et al. 2008). The Quickhull algorithm requires  
20 continuous values in the species-traits matrix. Therefore, we transformed our presence-  
21 absence species-matrix, into a "pseudo" species-traits matrix with continuous trait values.  
22 This was undertaken by calculating Jaccard's coefficient on the presence-absence traits matrix  
23 and by computing a Principal Coordinate Analysis (PCoA), on the Jaccard distance matrix  
24 (Villéger et al. 2008). We verified that the structure of the original species-traits matrix was  
25 correlated with the pseudo species-traits matrix, using a Mantel correlation test between the

1 Jaccard distance matrix calculated on the original data and an Euclidean distance matrix  
2 calculated on the pseudo matrix. The correlations were, respectively, 0.978 and 0.987 for the  
3 complete and the subset datasets.

4 Illustration of the functional richness was carried out by plotting a 3D graph of the  
5 first three axes of the Principal Component Analyses (PCA), calculated on the species-trait  
6 matrices of each dataset. Cluster analyses and computations of the indices (diversity and  
7 functional richness) were carried out using R software (Team 2008). Scripts from the S.  
8 Villéger and available online (<http://www.ecolag.univ-montp2.fr/software>) were used to  
9 compute the *FRic*. A 3D plot was undertaken using *do3d*, a wrapper for *scatterplot3d*  
10 developed by A. Culhane in the *made4* library.

## 11 Results and Discussion

### 12 *1<sup>st</sup> and 2<sup>nd</sup> consumers of the coastal food web*

13 The Shannon diversity index computed on the (species densities pooled by) functional  
14 guilds indicated that the differences between the two datasets were controlled principally by  
15 the invertebrate taxa (Fig. 2). These differences were supported also by the taxonomic  
16 differences between the two datasets. For instance, invertebrate taxa accounted for nearly  
17 10% of the total density in the complete dataset, whereas it represented over 70% in the  
18 subset dataset. Concurrently, the relative biomass displayed similar trends, with the  
19 invertebrate accounting for 51% of the total biomass in the complete dataset and 98% in the  
20 subset dataset.

21 Cluster analyses have confirmed the 'commonsense' expectations, that a greater  
22 number of functional traits were surveyed when all the trawled species ("complete" dataset)  
23 were included in the analyses. Four groups of traits were identified using the "complete"  
24 dataset, whereas only two groups were found using the "subset" dataset (Fig. 3). The two  
25 groups displayed by the "subset" dataset showed some similarities with two of the four

1 groups of the “complete” dataset. The first group of traits that was identified commonly by  
2 the two datasets was composed of omnivores and deposit feeders, seasonal migrants  
3 preferring mixed and vegetal substrates (Group A, in Fig. 3). The second group included  
4 marine juvenile migrants feeding on invertebrates (crustaceans and molluscs) or fish and  
5 preferring fine substrates (Group B, in Fig. 3). That second group included also the phyto-  
6 and zooplanktivores, in the “complete” dataset. The two other groups identified using the  
7 “complete” dataset, but absent from the “subset” dataset were observed. These groups were  
8 composed, respectively, of crawlers and detritivores, preferring mixed substrates (Group C, in  
9 Fig. 3), and plankton-deposit feeders and burrowers, preferring fine sediment as substrate  
10 (Group D, in Fig. 3).

11 Estimation of the *FRic*, i.e. the volume occupied by the species in the traits space,  
12 indicated that the coastal community as defined with the complete data set ( $FRic = 39.25$ )  
13 occupied 6.3 times more functional space, than the community characterized by the subset  
14 dataset ( $FRic = 6.20$ ). When illustrated in the species-traits ordination (Fig. 4), the  
15 comparison between the two datasets has indicated that the feeding guilds composed of the  
16 planktivores and deposit feeders (PL, PD) were under-represented in the subset dataset (see  
17 the cloud of white points, at the front of Fig. 4).

18 Results from the cluster analyses, the computation and the graphical representation of  
19 the *FRic*, suggest that the functional loss of information was associated mainly with the  
20 feeding traits and, more precisely, with organisms composing the 1<sup>st</sup> and 2<sup>nd</sup> consumer levels  
21 of the coastal nursery food web. Overlooking the primary (zooplanktivores and suspension  
22 feeders) and secondary consumers (detritivores-scavengers) in coastal and estuarine nursery  
23 habitats likely influences the understanding of that ecosystem functioning. For instance, most  
24 of the primary consumers are found on the bed of the estuary, where a rich benthic  
25 community develops (Mcclusky and Elliott 2007). Although the trophic interaction between

1 the bacteria-rich detritus and deposit feeders is considered as the dominant source of energy  
2 in the estuary, zooplanktivores and suspension feeders also play an important role, in linking  
3 the benthic and pelagic (water column) cycles (Baird and Ulanowicz 1993). Planktivores trap  
4 nutrients and food particles, which are afterwards deposited partly as undigested material on  
5 the bed, thereby supporting important densities of deposit feeders. However, the relative  
6 contribution of the planktivores, to the overall productivity of estuaries, varies with the  
7 turbidity conditions and water column dynamics of these ecosystems; it may represent  
8 between 41-86% of the total biomass, in certain less-turbid ecosystems (Herman et al. 1999).  
9 As for the detritivores and scavengers, they commonly constitute high biomasses in estuarine  
10 ecosystems. Being an important part of the detritus-benthic cycle, they interact (i.e. predation  
11 and competition) with other 2<sup>nd</sup> consumers and serve as food supply for 3<sup>rd</sup> consumers, such  
12 as large fish and birds (Mcclusky and Elliott 2007).

### 13 ***Functional redundancy***

14 The proximity and the overlap of the species (the white points, in Fig. 4) in the  
15 complete dataset, in comparison with the subset dataset suggest greater functional redundancy  
16 in the former dataset. For instance, the functional groups composed of detritivores-omnivores  
17 crawlers (DS, OM, CR) was characterized notably by epibenthic taxa, *Ophiura ophiura*,  
18 *Asterias rubens*, and Paguridae, absent from the subset dataset. Besides missing important  
19 components of the estuarine food web, these results suggest also that the exclusion of  
20 epibenthic fauna, in coastal analyses, may lead to an underestimation of the functional  
21 redundancy in these ecosystems. Redundancy is a desirable property of ecological  
22 communities, because it guaranties that specific ecosystem functions (e.g. nutrient trapping)  
23 will be maintained, in the case of species removal from that ecosystem (Micheli and Halpern  
24 2005). In redundant communities, the disappearance of one or more species would not affect  
25 the ecosystem process, because species represent “redundant information” with respect to that

1 process. Redundancy could be particularly important in coastal ecosystems, because these  
2 communities are under multiple pressures (natural and anthropogenic) and the probability of  
3 losing vulnerable species and hence essential ecosystem functions, is likely to be high.

#### 4 Conclusions

5 This study has addressed the question of what are the functional gains of including  
6 epibenthic species in coastal nursery analyses? Classification analyses of the functional traits  
7 showed that the addition of the epibenthic species, within the analyses, strengthens the  
8 functional understanding of these ecosystems, notably by adding primary and secondary  
9 consumers of the coastal food web. Thus exclusion of these species may lead to an  
10 underestimation of the functional redundancy of these ecosystems.

#### 11 Acknowledgments

12 This study was supported partly by the European programme IMAGE and the French  
13 research agency (ANR), under the project AMPHORE. The authors are grateful to P.  
14 Laffargue and J. Lobry for the map files of the Bay of Vilaine. They thank all the scientists  
15 and crews of the *R.V. Gwen Drez*, who participated to the sampling cruises undertaken  
16 between 2000 and 2005. Thank you to the anonymous reviewers who greatly enhanced this  
17 Note with their comments and editorial suggestions.
