Abstract:

Human fecal wastes contain a large variety of viruses that can enter the environment through discharge of waste materials from infected individuals. Despite the high diversity of viruses that are introduced into the environment by human fecal pollution, only a few have been recognized to cause disease in association with consumption of contaminated shellfish. To explain bivalve mollusks contamination, several factors including human epidemiology, virus persistence through sewage treatment plant, and shellfish uptake may be suggested. Considering different outbreaks described in the literature, the most common route for transmission is accidental contamination after heavy rainfall, when extra loads cause an overflow, and release of untreated sewage into the aquatic environment. Outbreak analysis also demonstrates the impact on shellfish consumption of some viral strain transmission and thus their impact on molecular epidemiology, especially for norovirus. To limit shellfish contamination and thus to protect the consumer, the most desirable and effective option is to reduce the viral input.

Introduction.

Shellfish were identified as a vector for human enteric pathogen transmission more than 150 years ago. The practice of consuming either raw or undercooked shellfish can lead to transmission of disease, as human pathogens can accumulate in the shellfish, during their filter-feeding activity. Contamination of shellfish-growing waters with human sewage was recognized as a contributing cause of the outbreaks, leading to the development of bacteriologic criteria to assess the impact of sewage on shellfish and shellfish-growing waters. The institution of regulations to specify acceptable levels of bacterial enteric pathogens in shellfish tissues (European regulation 54/2004/EC) or in waters where shellfish are grown (United State Sanitation program) led to the classification of production areas and assisted in lowering the number of bacterial outbreaks. However gastroenteritis or hepatitis outbreaks linked to shellfish consumption still occur as viral contamination is not yet controlled.

Source of pollution for human enteric viruses.

A large diversity of viruses may enter the environment through the discharge of waste materials from infected individuals. Enteric viruses, originating from human excreta, cause a wide spectrum of illnesses in man including hepatitis, gastroenteritis, meningitis, fever, rash, and conjunctivitis. Viruses most frequently implicated in outbreaks (hepatitis A virus and norovirus) are reviewed in detail in this special issue (Pintó et al., Atmar et al.). Thus, only a brief description of the principal viruses that have been characterized either in outbreaks or in field studies is given below. Most human enteric viruses induce gastroenteritis either in children or all age groups. Rotaviruses are the main etiological agent of viral gastroenteritis in infants and young children (Estes et al. 2007). They are an important cause of mortality in developing countries, while in the developed world they remain an important cause of morbidity and of hospitalization in young children. They are also increasingly recognized as a cause of infectious diarrhea in adults as well (Anderson et al. 2004). Other viruses, such as astrovirus or adenovirus, give mild symptoms, so their prevalence in the population is not well documented. Poliovirus which causes a devastating neurological disease, is a human enterovirus that, despite vaccination campaigns, is still present in some parts of the world. Other enteroviruses species cause a variety of other clinical syndromes, including respiratory infections, haemorrhagic conjunctivitis and myocarditis (Pallansch et al. 2007). Characteristics of these viruses are summarized in Table 1. Ill people shed norovirus at high levels (5×10^8 to 1.6×10^{12} RNA copies /g of stool (Atmar et al. 2008). Additionally, post-symptomatic virus shedding may continue for some time after disease, as demonstrated for enterovirus, hepatitis A virus, and norovirus (Atmar, et al., 2008; Costafreda et al., 2006; Pallansch et al. 2007). For example, norovirus shedding in an experimental human infection model lasted a median of 28 days, with a range from 13 to 56 days, and most subjects were no longer symptomatic by day 4 (Atmar et al. 2008). These data suggest that the impact of continued virus

shedding from ill and post-symptomatic patient on sewage may be very significant. Enterically-transmitted hepatitis viruses are distributed worldwide with no clear seasonal pattern, and transmission is linked to sanitary and living conditions of the population (Pintó & Saiz, 2007). Concentrations of 3×10^5 to 5×10^{11} RNA copies/g of stool have been reported for HAV (Costafreda et al. 2006.).

The regular and predictable pattern of seasonal outbreaks dominates the epidemiology of many exclusively human pathogens (Dowell et al. 2001). The seasonal infection may vary between different pathogens, but the timing and characteristics of the annual outbreak of a single pathogen are remarkably consistent from year to year. More general parameters, such as global climate change, may also have an impact on outbreak seasonality and strain transmission (Rohayem 2009) and the overall impact of environment on infectious diseases needs to be considered (Sansone 2009). For example a clear peak of norovirus outbreaks occurs during cold weather months on several continents, with lack of UV, cold temperature, frequent run-off being some of the possible explanations of extensive transmission (Mounts et al. 2000). However, noroviruses continue to circulate endemically throughout the year, and although there is the theoretical possibility of zoonotic spread, currently there is no direct evidence of the existence of a reservoir for re-introduction into the human population (Lopman et al. 2008). Gastroenteritis from all causes predominates during colder months of the year but it does not disappear during summer (Dowell et al. 2001; Lopman et al. 2008). It is now evident that some viruses may be detected all year long, either in sporadic cases of illness or in untreated sewage (da Silva et al. 2007; Patel et al. 2008).

Human enteric viruses, being very resistant, may persist in outflow water after treatment in sewage treatment plant. Indeed, they have been frequently detected in treated waters and surrounding rivers. Although wastewater is treated for the purposes of removing bacterial and viral pathogens, treatment is not 100% effective and wastewater effluent may contain enteric viruses that can contaminate the environment. Concentrations of hundred to thousands genomic copies per liter of treated wastewater can be detected, and seasonal variability is similar to that seen for untreated sewage. Several studies reported a higher frequency of genogroup I (GI) norovirus strains in treated effluent compared to genogroup II strains (van der Berg et al. 2005; Myrmelet et al. 2006; da Silva et al. 2007; La Rosa et al. 2007). Haramoto et al. (2006) even reported that all treated sewage samples were positive for GI. GI noroviruses are more resistant to inactivation and removal during the sewage treatment process, though the cause is unclear and should be studied in the future. Some hypothesize that differences in capsid proteins or binding properties may be responsible for different treatment efficiencies amongst norovirus types. Furthermore, GI noroviruses are more often implicated in shellfish- and water-related outbreaks than GII, suggesting that GI has a higher resistance to inactivation in the environment (Lopman et al. 2004; Blanton et al. 2006). Overall noroviruses are found in concentrations ranging from undetectable to 10^6 genome copies/l of treated wastewater (Pusch et al. 2005; van der Berg et al. 2005; da Silva et al. 2007; Iwai et al. 2009). One study reported that sapovirus was found at concentrations of about 0.5 to 1.8×10^2 genomic copies/liter (Haramoto et al. 2008b). Sewage analysis

1 showed that noroviruses and sapoviruses may be detected in treated water all year long (da Silva et al.
2 2007; Iwai et al. 2009).

3 Information on virus sources and virus levels in treated wastewaters can be used to estimate the
4 quantities of virus discharged into the environment. Limited data are available to calculate “virus
5 based-flow” or “event-flow” discharges into rivers or estuaries. Nevertheless, recent data suggest that,
6 during non-epidemic periods, less than 10^3 - 10^4 genomic copies/liter of norovirus are present in treated
7 wastewaters. During the epidemic period (winter) the concentration is probably 100- to 1000-fold
8 higher. The rate of reduction of virus concentrations through sewage treatment processes rely on the
9 initial raw sewage concentrations and residence time (Le Cann et al. 2004; Myrmel et al. 2006;
10 Katayama et al. 2008). Many types of wastewater treatment technologies exist and thus performance
11 may be different (da Silva et al. 2007). Viral elimination depends on a wide array of factors, including
12 temperature, solar radiation, adsorption, enzymatic destruction, and predation by bacteria and
13 protozoa. Removal mechanisms are complex and difficult to elucidate, especially for non-culturable
14 viruses. For example association of norovirus to particles has important implications as this may
15 protect viruses from inactivation by shielding, or enhance inactivation by photosensitization of
16 adsorbed macromolecules (da Silva et al. 2008). These data imply that viruses are discharged into
17 environmental waters with a seasonal profile and raises questions about the frequency and duration of
18 such peaks and the importance and impact of storm events that result in a bypass of wastewater
19 treatment during high flow epidemic periods. In the absence of precise information, calculations from
20 epidemiological data suggest that 10^6 norovirus fluxes can be expected from a town of 60,000
21 population-equivalent during winter outbreaks (Pommeuy et al. 2004). Many environmental factors
22 can have an impact on viral distribution, including currents, estuaries, and tides (Pommeuy et al.
23 2005b).

24 Norovirus is detected in surface waters less frequently than in wastewaters, probably due to dilution
25 and/or sedimentation mechanisms occurring during transport in rivers. Norovirus has been detected at
26 frequencies ranging from 5.8% in a Brazilian river to 53% in Japan (Haramoto et al. 2008a;
27 Miagostovich et al. 2008). Peak norovirus concentrations of up to 10^4 genome copies/liter of surface
28 waters have been reported, suggesting that the risk of infection can vary quantitatively as well as
29 qualitatively (Lodder et al. 2005; Westrell et al. 2006). Other human enteric viruses have also been
30 detected at various concentrations as noted in a recent review (Gerba 2007). For example, hepatitis A
31 virus is endemic in parts of Italy, and viral RNA has been detected at concentrations ranging from 75
32 to 730 genomes/liter in Venetian canals (Rose et al. 2006).

33 Despite efforts to reduce the pollution, human activities produce wastes that are discharged into the
34 sea. When entering in the sea, the free- or bound-microorganisms are subjected to dilution and bio-
35 sedimentation processes.

When discharged in the marine environment, microorganisms are subjected to different factors (Figure 1):

- Physical dilution dispersion and sedimentation decrease fecal contamination in coastal areas.
- Physio-chemical conditions, specific to marine water (sunlight radiation, salinity, temperature, pH) may influence viral degradation.

Figure 1: Main factors involved in viral behavior (Pommepeuy M. 2005a).

In coastal areas, boats or vessels could also have a significant impact on water and sediment contamination. In a study, fecal load sheds by bathers ranged from 10^{11} to 10^{16} viruses for 7185 bathers, during the weekend (normal and worst case condition, respectively) (Gerba 2000). The presence of fecal contamination in the environment is the result of flux mixing, accumulation in sediment and shellfish, and microbial persistence. It is important to take the complexity of the coastal environment into account to better understand the behavior of microorganisms in the ocean and the occurrence of pathogens in water, sediment or shellfish. Viral degradation in the sea depends on climatic conditions (e.g. temperature and sunlight exposure). Virus inactivation is considered to proceed as a first-order rate process. The rate of degradation, which encapsulates the effects of a number of different environmental factors, is given by T90, the time for viral concentration to decrease by one log (Schijven et al. 2010). Viruses in marine water are more persistent than *Escherichia coli*, as demonstrated by T90s values: *Escherichia coli* (5 h-3.5 d) Poliovirus-1 (10h- 7 d); Hepatitis A virus (3 d-28 d) Astrovirus (16-30 d) (Pommepeuy et al. 2005a). Virus attachment to colloid depends on their intrinsic properties (size, electric charge) and then may settle down in the shallow beds of the estuary side. Viruses bind to small size sediment or silts, especially when salinity is low, and they may persist in an infectious state for several months, protected by marine sediments in estuarine waters (Metcalf et al. 1983; Bosch A. 1988; Chung et al. 1993).

Shellfish contamination

1 Shellfish pump water over their gills and suspended particles are captured and passed on to the
2 alimentary tract. However, some sorting of particles occurs prior to ingestion to help regulate what is
3 presented to the digestive tract. Food particles enter the stomach through the short esophagus, and
4 particles are sorted further according to size, density and digestibility. The ciliary action of epithelial
5 cells sorts the particles in the stomach as follows: small and heavy (or excess) particles are
6 immediately rejected through the intestinal groove to the midgut while larger or lighter particles are
7 recirculated for further degradation. Food particles are embedded in mucous strings from the
8 esophagus and are carried forward by the rotation of the crystalline style and subjected to mechanical
9 and chemical (mainly glucanases) degradation. Small particles and insoluble molecules enter the
10 digestive gland via the brush-border of the ducts. A second phase of extracellular digestion occurs in
11 the lumen of the tubules, where extracellular enzymes are present. However, intracellular digestion is
12 the main digestive process in this part of the alimentary tract, and then nutrients are transported to the
13 hemolymph, amoebocytes and periglandular connective tissue. Undigested remnants accumulate in
14 residual bodies. In the final phase of the digestive process, the digestive cells break up to release their
15 apical pole filled with residual bodies and lysosomes and are expelled into the lumen of digestive
16 tubules, thereafter reaching the stomach via the ciliated duct section. Waste products are passed on to
17 the rectum via the intestine, where digestion and absorption of some nutrients may also occur
18 (Shumway et al. 1985; Gosling 2003).

19 It was generally thought that oysters act as mere filters or ionic traps, passively concentrating
20 particles such as bacteria or virus. However, unlike enteric bacterial species, enteric viruses persist in
21 shellfish for an extended period of time. It is this persistence that appears to result in its significant
22 impact on public health. Viruses are principally concentrated in the pancreatic tissue, also called
23 digestive diverticula. A number of different mechanisms have been suggested to explain differences
24 between in virus accumulation between different oyster species, including mechanical entrapment and
25 ionic bonding (Di Girolamo et al. 1977; Metcalf et al. 1982; Schwab et al. 1998; Burkhardt et al.
26 2000). Virus accumulation in oysters can also depend on factors such as water temperature, mucus
27 production, glycogen content of the connective tissue, and gonadal development. The importance of
28 secreted acid mucopolysaccharides in the concentration of poliovirus was first demonstrated 30 years
29 ago (Di Girolamo et al. 1977). Mucus present on gills was also suspected to be important for
30 concentration of reovirus by oysters (Bedford et al. 1978). Later hepatitis A virus was demonstrated to
31 persist for several weeks after bio-accumulation, with infectious virus being detectable after three
32 weeks and viral RNA still being detectable after six weeks using molecular assays (Kingsley et al.
33 2003). Infectious adenovirus was still detected in mussels for three weeks following bioaccumulation
34 and in oysters for six weeks (Hernroth et al. 2007).

35 Virus-like particles (VLPs) have been used to study virus persistence in shellfish. Using
36 rotavirus VLPs in oyster bioaccumulation studies, viral particles persisted in oyster tissues for from
37 one to three months, depending on the input concentrations (Loisy et al. 2005). We used VLPs of the

prototype genogroup I Norwalk virus (rNV VLP) and native Norwalk virus for bioaccumulation in oysters (*Crassostrea gigas*) to study norovirus persistence. We observed no differences in virus distribution between the native Norwalk virus and the VLPs, confirming that VLPs are good surrogates of infectious virions for this type of study. Interestingly, virus particle and VLP binding depended on specific cell types, such that some viral particles were detected in phagocytes located either in the epithelium or in the connective tissue (Le Guyader et al. 2006b). This observation might reflect the process of virus elimination or of normal digestion, but it is unclear if the immunoreactive material detected in phagocytes corresponds to particles being degraded and digested or whether particles are able to escape digestion. Specific binding to the main ducts in the digestive tract was observed and may be a mechanism for many viral particles to avoid entering in the food circulation and thus subsequent degradation (Le Guyader et al. 2006b). The existence of a specific attachment to oyster cells and the internalization into phagocytes could explain the difficulty in using depuration to rid oysters of viruses.

Human susceptibility to norovirus infection depends upon the presence or absence of certain carbohydrates of the ABH, secretor and Lewis histo-blood group families (Tan et al. 2007). Using the tissues sections of oyster bodies, we observed that the recognition of oyster digestive epithelial cells by rNV VLPs also involves carbohydrates. Similar to what was observed with human histo-blood group structures, the use of human saliva to inhibit VLP attachment to oyster tissues or the use of mutant VLPs that abolish VLP binding to histo-blood group antigens (alanine substitution at positions H329A and W375A) prevent binding to oyster tissue. Additional studies showed that the oyster ligands are similar to histo-blood group A. Thus, Norwalk virus binds to oyster tissues through an A-like carbohydrate structure, a binding site also used for attachment to carbohydrate on human epithelial cells (Tan et al. 2007). Norovirus VLPs can also specifically bind to tissues of other oyster species (*Crassostrea virginica*, *Crassostrea sikamea*) or clams (*Venerupis virginica*) or mussels (*Mytilis edulis*) (Tian et al. 2007). Genetic diversity of NoVs is reflected in their binding capacity to various histo-blood group antigenic structures. Distinct norovirus strains belonging to both genogroup I and II exhibit various binding patterns with different carbohydrate structures of the histo-blood group family, suggesting a possible coevolution of this group of viruses and their host or carrier vector (Le Pendu et al. 2006; Tan et al. 2009). Differences observed between GI.1 and GII.4 binding to human HBGAs are also present in oyster tissues. The distribution of GII.4 is not restricted to digestive tissues as for GI.1 and binds to the different organs using two different ligands (Maalouf et al. submitted). This is in accordance with reports demonstrating the presence of GII.4 in gills, albeit to a lower extent than in digestive tissues (McLeod et al 2009).

Outbreaks descriptions with a focus on the source of the contamination.

Despite the high diversity of viruses that are introduced into the environment by human fecal pollution, only a few have been recognized to cause disease in association with the consumption of

1 contaminated shellfish. Potential explanations for this observation, include a lack of susceptibility of
2 the persons consuming the shellfish to these viruses (*i.e.*, pre-existing immunity), a requirement for
3 exposure to higher doses than are present in the shellfish to establish infection, and a lack of
4 recognition of disease either through under-reporting or the unavailability of sensitive diagnostic
5 assays. Regulations specify acceptable levels of bacterial enteric pathogens in shellfish tissues or in
6 shellfish growing waters in Europe (European regulation, 91/492/EC) and the United States (National
7 Shellfish Sanitation Program). As depuration failed to eliminate viral contamination (see Richards et
8 al. same issue), some shellfish collected from B area have been implicated in outbreaks (Table 2).
9 However, in many outbreaks, the shellfish and shellfish-growing waters met regulatory criteria for
10 fecal bacterial levels, suggesting an accidental contamination event rather than exposure to a
11 continuous sewage discharge. Frequently the source of accidental events for shellfish contamination
12 cannot be traced (Shieh et al. 2000; Le Guyader et al. 2003.; Prato et al. 2004), but a number of reports
13 have been able to elucidate the cause of human fecal pollution (Table 2). Few outbreaks refer to oyster
14 collected in contaminated area (Ng et al. 2005) or people collecting oyster in non-classified area
15 (Sugieda et al. 1996).

16 The most common route for accidental contamination is sewage overflow and discharge into the
17 aquatic environment during heavy rainfall events. As mentioned above, untreated sewage is likely to
18 be heavily contaminated by enteric viruses. An Australian oyster-associated gastroenteritis outbreak,
19 affecting 2000 persons during the summer in 1978, was the first clear demonstration of this link
20 (Murphy et al. 1979). This outbreak was linked to sewage contamination of the oyster harvesting area
21 near Sydney following heavy rainfall, although not exceptional as similar or greater amounts were
22 recorded several times in the past 25 years. One explanation was possible increased urbanization
23 around the producing area (Murphy et al. 1979). Runoff from heavy spring rains were also suspected
24 to be responsible for 103 clusters of norovirus gastroenteritis involving more than 1000 persons after
25 clam or oyster consumption in New York State in 1982 (Morse et al. 1986). In south of France, heavy
26 rainfall and sewage treatment plant failure were twice implicated as the cause of large gastroenteritis
27 outbreaks due to consumption of oysters harvested from a single lagoon (Le Guyader et al. 2006a; Le
28 Guyader et al. 2008). Before the first outbreak, up to 150 mm of rainfall occurred in less than one
29 week, resulting in runoff and river overflow and sewage treatment system failures. Before the second
30 outbreak up to 76 mm of rain fell in one day, much more than the monthly average of 65.18 mm
31 shown by data collected over the previous 43 years (Le Guyader et al. 2008). Heavy rain causes the
32 storage capacity of the sewage treatment plant to be exceeded. In combined sewer and rainfall
33 systems, this leads to storm spills. Such discharges result in the release of untreated, heavily
34 contaminated effluent. This may be particularly true during the „first flush’ and this latter outbreak
35 was remarkable by the high diversity of human enteric viruses (up to six different strains) detected
36 both in patient stool and shellfish samples (Le Guyader et al. 2008).

Considering norovirus shellfish-related outbreaks, strains transmitted are frequently different from those circulating during community outbreaks. If we consider outbreaks giving precise strain identifications, NoV GI may constitute up to 30% of the strains detected in patients stools or shellfish samples (Kageyama et al. 2004; Gallimore et al. 2005; Le Guyader et al. 2006a; Le Guyader et al. 2008). For several years, norovirus GII strains, mainly those of the GII.4 cluster, have been the predominant (up to 95%) viruses detected (Lopman et al. 2008). This high prevalence of GII.4 NoV in the human population may be related to their mode of transmission, since they appear to be mainly transmitted via person-to-person contact in community outbreaks (Siebenga et al. 2009). Other humans strains, and importantly GI strains, are more often transmitted via food, especially oysters, or environmental contamination (Noda et al. 2008; Lysen et al. 2009). Fecal viral loads, which are higher for GII compared to GI strains (Chan 2006), shedding by asymptomatic subjects (Atmar et al.2008), and distinct behaviours during waste water treatments (da Silva et al. 2007) may partially explain some of the observed differences between GI and GII epidemiology (Table 2). In any case, this highlights the importance of food - related outbreaks in molecular epidemiology of norovirus.

The long incubation period of hepatitis A complicates linkage of this agent to particular food exposure incidents, thus few data are available. An outbreak in an Italian school was traced to a family that used to consume clams collected from a contaminated area. Parents and children, two of whom attended the school, were infected and then transmitted the disease to other children, but no information on shellfish contamination was provided (Leoni et al. 1998). In Italy, several outbreaks have been linked to illegal storage of shellfish in seawater tanks. There was no further information on the initial source of the contamination (Pontrelli et al. 2008). A sizeable hepatitis A outbreak in the USA in 1973 was linked to Louisiana oysters. The harvesting areas were flooded by the Mississippi River, and there was evidence of sewage contamination based on elevated fecal coliform levels that led to closure of the oyster beds. Subsequently, the oyster beds were reopened to harvesting, but the hepatitis A virus was retained in shellfish for six weeks following the event. At the time of harvesting, oysters were fully compliant with the US sanitation program standard, but were still contaminated with the virus. Unfortunately, no shellfish related to the outbreak could be analyzed (Mackowiak et al. 1976). In 1988 in Shanghai, China, almost 300,000 hepatitis A cases were traced to the consumption of clams harvested from a sewage-polluted area, without any further details on the cause of the contamination (Halliday et al.. 1991). Many other hepatitis A outbreaks linked to bivalve shellfish have been reported but the initiating fecal contamination event has been generally difficult to identify due to the protracted incubation period for this disease (Pintó et al. 2007). Contamination, due to disposal of faeces from infected individuals from boats, was shown to be the cause of a large gastroenteritis outbreak (Kohn et al. 1995). Epidemiological investigation showed that the outbreak resulted from disposal of human diarrheal stool from a single ill individual directly

1 into the waters over the shellfish bed (Kohn et al. 1995). This identification of at least one oyster
2 harvester with evidence of recent gastroenteritis infection was the presumable explanation for the
3 contamination of several tons of oysters leading to illness among shellfish consumers in five states in
4 the US (Dowell et al. 1995). Considering the high concentration of virus shed in stool and the low
5 infectious dose, such scenario is plausible (Atmar et al. 2008; Teunis et al. 2008). Such contamination
6 was again hypothesized following a hepatitis A outbreak in the US but without any precise
7 documentation, as the long incubation made data collection difficult (Shieh et al. 2007).

8 Regarding outbreak descriptions, illegal actions may play an important role in causing outbreaks,
9 though the initial cause of contamination is often difficult to identify.

10 One of the first cases implicating illegal activities in a outbreak involved oysters collected in an
11 unapproved area and implicated in hepatitis A cases (Desenclos et al. 1991). A possible fraud with
12 registration documents was suggested in Denmark (Christensen et al. 1998). Recently, in Sweden,
13 oysters collected in a clean area as defined by European regulations, but kept for several days in a
14 guest-harbor (forbidden regarding European regulation 54/2004/EC) were implicated in several cases
15 of gastroenteritis (Nenonen et al. 2009). A hepatitis A outbreak in Italy was caused by mussels that
16 had been kept in sweater tanks for a long time (Lopalco et al. 1997). In France, an outbreak was
17 linked to oysters produced in a clean area, such that no environmental event could explain the
18 multiple contamination of the batch. Later, police arrested a fisherman illegally collecting oysters
19 from a forbidden area, who later admitted to selling them to the producer (Le Guyader et al. 2010).
20 This outbreak illustrates the danger of breaching regulations and refusing to consider the usefulness
21 of the producing area classification.

22 Other outbreaks reported in the literature referred to shellfish potentially exposed to microbial
23 contamination and sold for cooking. In the US, gastroenteritis cases were reported after the
24 consumption of raw clams in a restaurant. These clams, imported from China packaged and labeled as
25 cooked, had the physical appearance of raw clams and were found contaminated with human enteric
26 virus (Kingsley et al. 2002). In New Zealand, a large gastroenteritis outbreak was linked to oyster
27 consumption, labeled with an advisory to cook the product before consumption. However, these
28 instructions were not followed by the caterer (Simmons et al. 2007). In Australia, frozen imported
29 oysters served grilled were implicated in an outbreak highlighting the resistance of these viruses
30 (Webby et al. 2007). In Spain, two large outbreaks of hepatitis A were linked to the consumption of
31 lightly cooked coquina clam, demonstrating the high resistance of these viruses (Sanchez et al. 2002;
32 Costafreda et al. 2006; Pintó et al., 2009.). Very often, for imported frozen products, it is not possible
33 to identify the area of production from package labeling, emphasizing the need to harmonize
34 regulations.

1 Bivalve mollusk (mussels, oysters, clams, etc) production is the only animal aquaculture method that
2 is both environmentally friendly and sustainable. However the filter-feeding nature of bivalves, and,
3 thus, their tendency to concentrate any environmental or man-made contaminant present in their
4 growing waters, requires special attention to food safety issues and compliance with applicable
5 harvesting requirements. On the other hand, seafood is nutritious, tasty, and offers essential
6 components of a healthy diet. Additionally, in some countries, shellfish consumption is an integral part
7 of cultural culinary norms. Thus, it is important to prevent contamination to ensure good quality and
8 consumer safety. This may be performed by a better identification of the source of contamination,
9 understanding processes and mechanisms of virus uptake by mollusk shellfish, and learning about the
10 behavior of viral particles in shellfish tissues.

Table 1: Characteristics of the main enteric viruses.

Name	Size	Capside	Genome*	Incubation	Illness	Season
Adenovirus	70 nm	Complexe	DsDNA- 35,900 bp	3-10 days	gastroenteritis	All year
Aichi virus	27-32 nm	icosahedral	ssRNA- 8,251 bases	1-2 days	gastroenteritis	All year
Astrovirus	27-32 nm	icosahedral	ssRNA- 6,797 bases	3-5 days	gastroenteritis	Winter
Calicivirus	27-32 nm	icosahedral	ssRNA- 7,642 bases	2-3 days	gastroenteritis	Winter
Enterovirus	20-30 nm	icosahedral	ssRNA- 7,200 bases	7-30 days	diverse	Summer
Rotavirus	70 nm	Triple layer icosahedral	dsRNA, 11 genes (667 to 3,302 bp)	3 days	gastroenteritis	Winter
Hepatitis A virus	27-32nm	icosahedral	ssRNA- 7,478 bases	Up to 6 weeks	hepatitis	All year

* ds: double strand, bp; base pairs, ss: single strand

Table 2: Contamination events identified from different outbreaks linked to shellfish consumption worldwide.

Shellfish	Country	Category	# cases	Stool analysis	Shellfish analysis	Contamination events	reference
Oysters	Japan	-	-	NoV GI	NoV GI, GII	direct sampling on on a rocky beach	Sugieda et al., 1996
Oysters	Danemark	A	356	NoV, EV	NoV, EV	imported product, possible fraud with registration documents	Christensen et al., 1998
Oysters	France	A	14	NoV GI	NoV GI,	No environmental explanation (low E.coli counts)	Le Guyader et al., 2003
Oysters	US (CA)	A&B	171	NoV	NoV	No environmental explanation	Shieh et al., 2000
Oysters	US (LA)	A	132	NoV GI, GII	NoV GI	overboard sewage disposal	Kohn et al., 1995
Oysters	Singapore	B	305	NoV GII	NoV GII	potential contaminated area	Ng, et al., 2004
Oysters	France	B°	127	NoV GI.4,GII.4, b	NoV GI.4, GII.4, 8	flooding and sewage treatment plant failure	Le Guyader et al., 2006b
Oysters	Italy		202	NoV GI.6, 4 GII.4, 8			
Oysters	Australia	-	83	NoV GI.4, 2, GII.6,7,9,5,12	NoVGII.4	imported from Japan	Webby et al. 2007
Oysters	New zealand	C	115	NoV GI, GII.3, 6,12	NoV GI.3, GII.3, 6, 8, 7, 12	imported frozen for cooking preparation	Simmons et al. 2007
Oysters	Canada	A	135	NoV GI.1,2, GII. 3, 4, 5	NoV GI.2	widespread contamination	David et al. 2007
Oysters	Sweden	A	30	NoV GI.1	NoV GI.1, GII.3	inappropriate storage for 10 days in corf sunk in a guest-harbor	Nenonen et al. 2009
Oysters	France	A	205	AiV, AV, EV, RV, NoV GI, GII	AiV, AV, RV, NoV GI, GII,	flooding and sewage treatment plant failure	Le Guyader et al. 2008
Oysters	France	A	34	NoV GII.4, SaV, AiV	NoV GI,II.4 SaV	Illegal collection of oyster from a forbidden area	Le Guyader et al. 2010
Mussels	Italy	-	103	NoV	NoV GII & GI	No environmental explanation	Prato et al., 2004
clams	US	B°°	5	NoV	NoV GII, + HAV	Frozen imported product	Kingsley et al., 2002
Oysters	US	A	61	HAV	HAV	illegal harvest from an unapproved area	Desenclos et al., 1991
Oysters	US	A	39	HAV	HAV	illegal waste discharges from harvest vessels or recreational boats, illegal harvesting in closed areas	Sheih et al. 2007
Mussels	Italy	-	562	HAV	-	Probable contaminated area and shellfish storage in seawater tanks	Lopalco et al. 1997
Mussels, razor shell,	Italy	diverse	882	HAV	HAV	breeding farms from various area and illegal storage in seawater	Pontrelli et al. 2008

Clam	China	A	638*	HAV	HAV	contaminated growing area	Halliday et al., 1991
Clam	Spain	-	184	HAV	HAV	Frozen imported shellfish	Sanchez et al., 2002
Clam	Spain	-	100	HAV	HAV	Frozen imported shellfish	Costafreda et al. 2006.

- : data not specified, B°: depuration specified, B^{oo}: based on *E.coli* counts detected in the sample analyzed, * cases directly linked to clam consumption.

Category (A or B): sanitary classification of the sample based on *E.coli* detection in shellfish meat (EEC regulation) or in water (US regulation).
