Abstract:

Four time-series of copepod species biomass in the north of Spain were contrasted to demonstrate spatial autocorrelation of local communities and their responses to short-term local and regional variability in oceanographic conditions. The series represented coastal and oceanic environments along a marked gradient of influence of seasonal upwelling from Galicia to the Mar Cantábrico (S Bay of Biscay), and each one included at least 10 years of continuous data collected at monthly frequency. Community composition (i.e. species number and diversity) was very consistent through the region, but local variations in the presence of new species and the relative proportions of common species allowed for the characterisation of the response to the environment at each site. Small-sized species were more frequent near the coast. A few species, however, captured the main patterns of variability in all series. *Calanus helgolandicus* and *Acartia* (mainly *Acartia clausi*) were generally the main contributors to total biomass, while other species as *Paracalanus parvus* and *Clausocalanus* spp. were important only at some locations. Most copepod indices were positively correlated with upwelling, either considering the whole community (biomass, species richness and diversity) or individual species, but only in the coastal series analysed since 1991. Copepods in the nearby ocean, however, showed negative correlations with upwelling in the period 1960–1986. The effects of upwelling may have been modulated by local factors, as showed by the increases in biomass, number of species and diversity in associations with increases in sea surface temperature in Galicia, while in the Mar Cantábrico only the warming-tolerant species increased and those typical of upwelling decreased. Density stratification

1 of the water column was associated to decreases in total copepod biomass in Galicia, while it favoured the increase in
2 species richness in the Mar Cantábrico. Nearly all significant responses of copepods to environmental variability were
3 delayed for up to five months, showing the importance of considering time-lags in the analysis of temporal responses of
4 zooplankton.

5 **1. Introduction**

6 Copepods play a key role in pelagic ecosystems, representing > 90% of total abundance and biomass of
7 mesozooplankton and driving a large part of biogeochemical fluxes relevant for the sustaining of complex food webs
8 and the transfer of carbon to the sediments of continental shelves (Smetacek, 1988). Therefore, planktonic copepod
9 species are generally well known in most seas and form one of the most robust indicators of variability in long-term
10 research programs and time-series (Valdés et al., 2007).

11 Regional, climate-driven changes in zooplankton were recognized through the Atlantic and mostly related to the
12 warming of the surface waters producing increased stratification in the water column (Beaugrand et al., 2000, 2002;
13 Beaugrand, 2003, 2004; Richardson and Schoeman, 2004, ICES, 2006). Sub-regional and local modulation of the large
14 spatial and temporal trends, however, plays a key role in structuring the communities. Most of the variability in the
15 number of copepod species number and their densities relative to climatic and hydrological forcing was described in
16 plankton from boreal cold water areas, where the stabilization of the water column caused a major modification of the
17 environment (Beaugrand et al., 2000; 2002). Moreover, it seems likely that advective processes play a substantial role
18 and interact with the impact of climate on the hydroclimatic regime. Upwelling-downwelling cycles and shelf currents
19 were pointed out as the main sources of water-mass advection influencing zooplankton communities in the northeastern
20 Atlantic (Beaugrand, 2003). Increases in warm-water species (as *Temora stylifera*) were attributed both to transport
21 from southern waters and to local warming (Villate et al., 1997; Valdés et al., 2007). Similarly, local increases of
22 copepods in recent years could be explained by a reduction in the offshore transport of surface water during weak
23 upwelling periods (Bode et al., 2009). Such changes are consistent with the overall negative effect of increasing
24 stratification at annual scales (Valdés et al., 2007; Bode et al., 2009).

25 The northwestern shelf off the Iberian Peninsula offers an unique opportunity to study the variability in copepod
26 communities in a gradient of environmental change. Seasonal upwelling affects the coasts of Portugal and Galicia
27 (northwestern Spain), occasionally extending its influence to the Mar Cantábrico in the southern Bay of Biscay (Botas
28 et al., 1990). In the latter area, the seasonal cycle is characteristic of temperate regions, where the warming of surface
29 water triggers the development of summer stratification and winter cooling is responsible for most of annual mixing

1 (Botas et al., 1989; González-Pola et al., 2007). Upwelling, caused primarily by southerly and westerly winds during
2 spring and summer, drives most of the productivity in Galicia (Bode et al., 1996; Alvarez-Salgado et al., 2002), while
3 the spring bloom is the main productivity peak in the Mar Cantábrico (Bode et al., 1996; Llope et al., 2007). Poleward
4 currents, more intense during the autumn-winter transition (Alvarez-Salgado et al., 2003; Varela et al., 2005), also
5 contribute to the along shore transport of water and organisms between Galicia and the Mar Cantábrico (Fernández et
6 al., 1991; Bode et al., 2002). Copepod communities in this area have been studied mainly in connection to seasonal
7 cycles (Alvarez-Ossorio, 1977; Corral and Alvarez-Ossorio, 1978; Valdés et al., 1990; Valdés, 1993; Cabal, 1993),
8 however recent studies focussed on large scale variability related to climate (Villate et al., 1997; Valdés and Moral,
9 1998; ICES, 2006; Valdés et al., 2007; Bode et al., 2009). Besides hydrographic variability, nutrient inputs and plankton
10 composition and production were well described through this region (e.g. Casas et al., 1997; Llope et al., 2007) thus
11 allowing for a detailed analysis of local versus regional variability.

12 In this paper we compare time-series of copepod species biomass in the north of Spain with the aim of demonstrating
13 spatial autocorrelation of local communities and their responses to short-term local and regional variability in
14 oceanographic conditions. Copepod species were selected because they were consistently recorded for at least ten years
15 at three coastal sites in the north of Spain (Vigo, A Coruña and Santander). Continuous Plankton Recorder (CPR) data
16 for the same region (Galicia and S Bay of Biscay) were also included to account for variability in the nearby ocean.
17 Temporal trends, periodicity and cross-correlations on the series were analysed, as well as their relationships with
18 temperature, upwelling intensity and water column stratification.

19 **2. Materials and Methods**

20 2.1. Copepod samples

21 Copepod species were systematically recorded in the framework of project Radiales ([http://www.seriestemporales-
23 ieo.net](http://www.seriestemporales-
22 ieo.net)). For this paper, monthly time-series from three sites along the northern coast of Spain were selected (Fig. 1).
24 The series covered at least 10 years of monthly observations and a geographical gradient from the areas of more
25 persistent upwelling conditions (Vigo and A Coruña in Galicia) to more stratified conditions in the southern Bay of
26 Biscay (Santander, Mar Cantábrico). Data from one mid-shelf station (70-110 m depth, Table 1) was selected at each
27 site. In addition, we studied the copepod time-series obtained with the CPR program (<http://www.sahfos.org/CPR>) as
28 spatially-integrated mean values for the standard grid F4, representing copepod community composition from the
nearby ocean.

1 Details of zooplankton sampling procedures of both Radiales and CPR time-series can be found in Valdés et al. (2007)
2 and Richardson et al. (2006), respectively. Briefly, zooplankton from the Radiales series was sampled using 50-cm
3 diameter Juday-Bogorov plankton nets equipped with mesh size 200 μm (Vigo, A Coruña) or 250 μm (Santander).
4 Tows were double oblique from the surface to 5 m from the bottom, except in Santander where only the upper 50 m
5 were sampled. Samples were preserved in 2–4% sodium borate-buffered formaldehyde. All copepods (Vigo) or at least
6 1000 copepods per sample (A Coruña and Santander) were counted and classified at genus or species level. Growth
7 stages were recorded separately for most species. Initial values were reported as number of individuals per m^3 . For CPR
8 series, the self-contained automatic plankton recorder collects plankton continuously from a standard depth of ca. 7 m
9 (Hays et al., 1995). Samples were collected in a silk net of 270 μm mesh size and preserved with formalin. In this paper
10 we used mean abundance values for species recorded in the whole sample (eye count procedure in Richardson et al.,
11 2006) and scaled to numbers per m^3 by taking into account that individual CPR samples correspond to approximately 3
12 m^3 . To overcome the problem of overrepresentation of species of small body size present in large numbers, all
13 abundance values were transformed to biomass by first scaling mean species body length (e.g. Table 5 of Richardson et
14 al., 2006) to wet-weight (w-w) body biomass (Peters, 1983) and then by multiplying species abundance by species-
15 specific body biomass (Richardson et al., 2006). Values for species not included in the Richardson's et al. study and
16 those from the different growth stages of a given species were calculated from length data obtained from the literature
17 or measurements from actual samples (e.g. Valdés et al., 1990). This procedure allowed for comparison of concurrent
18 but slightly different time-series, because of small local variations in sampling and counting procedures, but it did not
19 intent to provide precise biomass estimates for a given species. A more detailed study of the distribution and variability
20 of actual biomass values of zooplankton species and groups in the study area is available in Valdés et al. (1990).
21 Species and total copepod biomass values were reported as mg w-w m^{-3} .

22 2.2. Environmental data

23 Sea surface temperature (SST) and upwelling indicators were obtained for each of copepod time-series locations. For
24 CPR F4 series, SST data were monthly averages of all observations available in two $1^\circ \times 1^\circ$ grids from the International
25 Comprehensive Ocean-Atmosphere Data Set (ICOADS, <http://dss.ucar.edu/datasets/>), representing the environment
26 conditions of Galicia (grid G in Fig. 1, centred at 42.5°N , 10.5°W) and of Mar Cantábrico (grid C in Fig. 1, centred at
27 44.5°N , 5.5°W), respectively. Favourable upwelling conditions in these areas were also represented by the alongshore
28 wind speed (m s^{-1}) in each area ($-v_G$ for Galicia and $-u_C$ for Mar Cantábrico). For the coastal series surface temperature
29 (5 m depth) measurements were obtained from CTD profiles concurrent with copepod sampling at the same stations. In

1 addition, stratification of the upper water column at these stations was represented by the σ_t increase from 5 to 50 m
2 measured in the same CTD profiles. The latter parameter was included instead of other measures of stratification, as the
3 standard deviation of temperature in the water column (e.g. Valdés et al., 2007), because of the lack of correlation
4 between temperature and salinity changes in stations from Galicia. Additional information of the environmental
5 variability at the sampling sites can be found in Casas et al. (1997), González-Pola et al. (2007) and Varela et al. (2006).

6 2.3. Statistical analyses

7 The relationship among copepod time-series was studied by multidimensional scaling (MDS) ordinations. First, Bray-
8 Curtis similarity values among observations were computed using biomass values of the dominant (>1% of total
9 biomass in at least one series) copepod species or groups. Values were transformed using the fourth-root
10 transformations (Clarke and Warwick, 2001). Second, samples in the resulting 2-dimensional MDS space were coded
11 according to the time-series to reveal spatial correlations, and the significance of the ordination was studied by
12 examining the averaged rank similarities between and within groups. Third, the most discriminating species and the
13 species characteristic of each series were identified. All these computations were made using the procedures Similarity,
14 MDS, SIMPER and ANOSIM from the PRIMER V. 5 statistical package (Clarke and Warwick, 2001).

15 Temporal variability of selected variables from each time-series was decomposed in linear, periodic and autocorrelation
16 components using a Box-Jenkins approach (Box and Jenkins, 1976; Nogueira et al., 1998). Each copepod time-series
17 was characterized by the total number of copepod species (S), including also rare species (<1% of total biomass), total
18 copepod biomass (B, mg w/w m⁻³), copepod diversity (H, Shannon) and the biomass of the three most discriminant
19 species present in all series. Finally, significant variance components (P<0.05) were removed before cross-correlation
20 analysis with similarly treated environmental variables. The significance of linear (trend) components, including
21 autocorrelation was assessed using ANOVA tests, while the significance of periodic components was determined using
22 the Fisher-G statistic (Swan and Sandilanks, 1995). Box-Jenkins analysis were made using MATLAB (Component Run
23 Time version 7.7).

24 3. Results

25 3.1. Species richness and biomass

26 A total of 79 copepod categories (excluding eggs and copepodites but including nauplii) were recorded. Full lists of
27 these categories can be consulted in Richardson et al. (2006) and Valdés et al. (2007). Only 16 copepod categories were
28 simultaneously observed at all series. The number of categories recorded was lower for the CPR series (36 categories)

1 than for the Radiales series (63, 44 and 39 for A Coruña, Vigo and Santander, respectively). To compare the series, 25
2 representative categories having >1% of total biomass recorded in at least one series were selected (Table 2). Categories
3 with <1% of total biomass were grouped as other copepoda.

4 *Calanus helgolandicus*, mainly young stages, and *Acartia* species, mainly *A. clausi*, showed the largest biomass values
5 in almost all series, representing on average between 17 and 30% of total copepod biomass (Table 2). In addition, other
6 species showed biomass contributions near 10%, but these secondary species were characteristic of each series. For
7 instance, *Centropages typicus* amounted on average 8% of total biomass in the CPR series, while in Vigo *Centropages*
8 *chierchiae* and *Pseudocalanus elongatus* had similar contributions. In A Coruña species contributions were more
9 balanced, with *Oncaea media* as secondary species (13% of biomass). In Santander, *Paracalanus parvus* (14%) and
10 *Dytrichocorycaeus anglicus* (11%) were the species contributing most to total biomass after *C. helgolandicus*, with
11 average values even higher than *A. clausi* (9%). The remaining species were much less abundant, with occasional
12 biomass peaks but in general with contributions to total biomass lower than 5%.

13 3.2. Spatial ordination of series

14 The MDS ordination of all copepod series reflected their geographic origin (Fig. 2). The largest variability was
15 exhibited by the CPR series, as the data covered a longer time period and spatial domain than the other series, while the
16 data from coastal series appeared far more grouped with large overlapping for Galicia series (Vigo and A Coruña).
17 Interestingly, a second MDS considering only the coastal series and also showing the large similarity between Vigo and
18 A Coruña, clearly allowed the separation of the observations from the Galicia series from those of Santander in the Mar
19 Cantábrico. The obtained ordinations were acceptable, as the stress values of both MDS plots were close to 0.2 (Clarke
20 and Warwick, 2001). For the initial ordination with all series, the value of the R statistic comparing the similarity
21 between and within series was significant ($R = 0.383$, $P < 0.001$), indicating that, on average, the observations within
22 each series were more similar to one another than observations from other series (Clarke and Warwick, 2001). Pairwise
23 comparisons of R between series also produced significant values (Fig. 3).

24 As the original biomass data were transformed to avoid the large contribution of dominant species in terms of
25 abundance, the separation among series was due to less abundant but characteristic species, with average contributions
26 to dissimilarity <10% (Fig. 3). *Paracalanus parvus*, *Oithona plumifera* and *O. media* were the main species
27 discriminating CPR samples from those of coastal series, as these species were not present in the former (Table 2).
28 Juvenile stages of *C. helgolandicus* were not recorded separately in Santander series and contributed to a large
29 percentage of dissimilarity among coastal series, suggesting an overestimation of the biomass of this species in

1 Santander. The separation of Santander series from those of Galicia, however, was due not only to *C. helgolandicus* but
2 also to changes in other species. For instance, *Clausocalanus* spp. was present in all series but reached high biomass
3 contributions in Santander and very low ones in Vigo. Further separation was due to *Paraeuchaeta hebes*, for Galicia
4 series, and *Eucalanus elongatus*, for A Coruña and Santander series (Fig. 3).

5 As we mentioned before for the analysis of the average biomass (Table2), *A. clausi* and *C. helgolandicus* were the
6 species with the largest contribution to within series similarity for CPR and Vigo series (Table 3). *A. clausi* also showed
7 the largest contribution to similarity in A Coruña, followed by *P. parvus*, while the contribution of *C. helgolandicus*
8 was relatively low. In Santander, *P. parvus* and *Clausocalanus* spp. showed the largest contributions to similarity.

9 3.3. Temporal variability

10 Univariate measures revealed also differences among series that can be attributed to both their spatial separation but
11 also to the time period covered by each series (Table 4). Mean values of the number of copepod species or categories
12 (S) and total biomass (B) were much lower for CPR series, even considering the two periods with continuous data, than
13 for coastal series. These differences can be explained by the location of samples of the CPR series, generally obtained
14 near the surface and far from the coast, while those of coastal series were depth-integrated. Diversity values, however,
15 were more similar among series, indicating an equivalent structure of the copepod community at all sites. Analysing
16 time components of the series, a few series showed significant linear trends with time (Table 4). Only the number of
17 species and diversity increased significantly in the CPR series during the period 1960-1986, while an opposite pattern
18 occurred at A Coruña between 1994 and 2006. Periodic components were only significant in the case of biomass and
19 only for some of the series, indicating the recurrent effect of annual seasons on copepods. Seasonal plots of these values
20 showed that the increase of species recorded in the CPR was concentrated mainly in the spring and autumn, even in the
21 most recent period (Fig. 4). Similarly, the largest decrease in species and diversity at A Coruña occurred also in these
22 seasons. Biomass changes, although with non significant linear trends, were also apparent in some series. For instance,
23 maximum annual values decreased in the CPR series, while autumn values increased in Vigo. The series of Santander
24 did not show significant year-to-year changes, however the seasonal pattern of univariate measures revealed that the
25 number of species and diversity were characteristically high during summer. In contrast, the series from Galicia
26 showed a more irregular distribution of high and low species and diversity values. Autocorrelation between adjacent
27 monthly samples was significant for the number of species (Table 4). Nevertheless, there was no significant
28 autocorrelation even at up to six month lag for any of the univariate measures analysed.

1 The biomass values of the main copepod species did not had significant linear trends with time, except for
2 *Clausocalanus* spp. from A Coruña and *C. helgolandicus* from Santander that showed decreasing biomass with time
3 (Table 4). *C. helgolandicus* juveniles and adults, considered as separate categories for the similarity analyses above,
4 were now combined into a single category for the time-series analysis. Significant seasonality was also shown by *C.*
5 *helgolandicus* and *A. clausi* in A Coruña, and by the latter species also in Santander, while there were no significant
6 periodic components for the main species in the remaining series (Vigo and CPR). Such seasonality was the
7 consequence of the concentration of annual maximum biomass values between March and October in both species. In
8 contrast, autocorrelation at one month lag was significant for at least one species in each series. In this way, *A. clausi*
9 displayed significant autocorrelation in all series except in Vigo and in CPR during the period 1960-1986. Similarly,
10 *Clausocalanus* spp. biomass was autocorrelated in Vigo and *C. helgolandicus* in Santander (Table 4). Although no
11 significant trends were observed a decrease in the maximum biomass values can be distinguished in the seasonal
12 distribution of values between the two continuous periods in CPR series (Fig. 5). Similarly, high biomass values of *A.*
13 *clausi* and *C. helgolandicus* (but not *Clausocalanus* spp.) were more frequent in recent years in Vigo while this increase
14 was not apparent for A Coruña.

15 3.4. Relationships with local and regional factors

16 Environmental conditions varied characteristically among sampling areas (Fig. 6). Surface temperature had both the
17 largest values and annual variance in the Mar Cantábrico whereas it had low values and variance in Galicia. Conversely,
18 upwelling favourable winds (positive values of both $-v_G$ and $-u_C$) were faster and more frequent in the latter than in the
19 former region. Despite the higher importance of upwelling and associated colder and well-mixed waters in Galicia,
20 likely due to the vicinity of the rias and inputs of freshwater, the stratification of the upper 50 m of the water column
21 was on average higher in the series of Vigo than in other coastal sites. Seasonality was evident in the series of
22 environmental variables, particularly those of temperature, accounting for up to 90% of total variance. In contrast, there
23 were no significant linear trends in monthly mean values.

24 Cross-correlation among prewhitened residuals of copepod and environmental variables was significant at zero lag for
25 a few cases, suggesting that most effects of environmental changes on copepods were delayed for one or several months
26 (Table 5). The sign of the correlations, however, varied among series as local conditions alter the influence of the
27 different factors on copepods. For instance, upwelling conditions were negatively correlated with copepod diversity,
28 biomass and *C. helgolandicus* with a delay from 2 to 4 months for the CPR series, and with the number of species in A
29 Coruña. In Vigo and A Coruña, however, the effect of upwelling was positive on total biomass and that of *A. clausi* and

1 *C. helgolandicus* measured 3 to 5 months later. Upwelling in the Mar Cantábrico was also related to 3 to 5 month
2 delayed increases in biomass and diversity at Santander, as well as increases of *A. clausi* and decreases of *C.*
3 *helgolandicus* in the most recent CPR series period.

4 The effects of temperature were generally positive on copepods with 1 to 4 month-lags, as found with total biomass,
5 number of species and diversity in the CPR and Galicia series (Table 5). For Santander, high temperature values were
6 related to concurrent high biomass of *C. helgolandicus* and *Clausocalanus* but also to decreases in *A. clausi* one month
7 later. Stratification was negatively correlated with biomass in Vigo and A Coruña at lags of up to 4 months. In contrast,
8 stratification showed positive correlations with *Clausocalanus* spp. at 3 month-lags in A Coruña, and with the number
9 of copepod species and the biomass of *C. helgolandicus* at one month-lag in Santander.

10 **4. Discussion**

11 4.1. Spatial continuity of copepod communities

12 The copepod community in the southern Bay of Biscay, including also waters of Galicia, has a transitional character
13 due to the presence of species characteristic of the nearby regions (Valdés et al., 2007). Our results support earlier
14 studies based on presence/absence or abundance data concluding the general homogeneity of species assemblages in
15 this region (Valdés et al., 1990; Cabal, 1993; Valdés, 1993), with local variations mainly related to rias, estuaries and
16 coastal habitats (e.g. Alvarez-Ossorio, 1977; Corral and Alvarez-Ossorio, 1978; Villate et al., 1997; Bode et al., 2005).
17 Valdés (1993) identified three main assemblages in this region: (I) species of general distribution, corresponding to the
18 type “shared” (Darlington, 1957) or “intermediate” species (Colebrook et al., 1961); (II) neritic-oceanic species, and
19 (III) species from rias and estuaries. The two last groups include the “transitional” species (Darlington, 1957) that are
20 dominant in a particular region but extend to nearby regions. Species of general distribution include those most
21 discriminant and characteristically varying among time-series, as *C. helgolandicus*, *A. clausi*, *P. parvus* and
22 *Clausocalanus* spp. The group also includes indicator species, generally not the ones with maximum abundance, but
23 typical of waters from boreal or subtropical areas (Corral and Alvarez-Ossorio, 1978; Valdés et al., 1990). *T. stylifera* is
24 an example of warm water species progressively expanding into the region in recent years (Villate et al., 1997; Valdés
25 et al., 2007; Bode et al., 2009). Because of the relatively narrow shelf and the highly dynamic environment caused by
26 the upwelling and water-mass advections in this region, most species belong to the neritic-oceanic group. Their
27 dominance, however, is generally lower than that of species in the first group, as evidenced in the average biomass
28 contributions of most species (Table 2).

1 Despite the variations in sampling sites, methods, counting procedures, and the different length of the observational
2 periods, all time-series analysed in this study revealed the high coherence of the copepod community in the number of
3 species, diversity and dominant species. A detailed discussion on the difficulties found when comparing zooplankton
4 time-series can be found in Valdés et al. (2007). Spatial differences, however, explain the ordination of the observations
5 in the MDS analysis, which closely resembles the actual geographical origin of each series (Fig. 2). Distance to the
6 coast is likely the main factor implied in the separation of CPR from coastal series, as found in studies considering
7 across-shelf distributions (Valdés, 1993; Cabal, 1993; Valdés and Moral, 1998). Habitat preferences of some species
8 also contribute to the characterisation of the series, as it occurs with the oceanic *C. typicus* vs. the neritic *C. chierchiae*
9 (Bonnet et al., 2007). In contrast, offshore export of coastal species by upwelling may contribute to the homogeneity in
10 the composition, as suggested by the relatively high dominance of *Acartia* spp. in both oceanic and coastal series.

11 Relatively large differences between CPR and Santander series can be explained because most samples for the F4 grid
12 in the former came actually from the western side of the grid (Richardson et al., 2006). The largest difference was found
13 between Vigo and Santander series, the end-members of the upwelling-stratification geographic gradient. Strong
14 coherence in the composition of zooplankton was also found in other studies comparing long time-series from the same
15 region (Beaugrand et al., 2002; Lavaniegos and Ohman, 2007).

16 Several statistical methods could have been employed as an alternative to MDS to show the spatial ordination of the
17 time-series in this study. Cluster analysis, for instance, was chosen to show the biogeographical associations of copepod
18 species in this NE Atlantic region using available check lists (Cabal, 1993; Valdés, 1993; Valdés et al., 2007). While the
19 cluster ordinations fitted well with the expected relationships and were well suited to compare data obtained by different
20 procedures (even semi-quantitative or presence-absence data), the results of cluster analysis were largely dependent on
21 the statistical decisions taken during the analysis. Therefore, the type of transformation applied to raw data, the
22 similarity or dissimilarity index, along with the grouping method, produce very different ordinations (Clarke and
23 Warwick, 2001). Even for quantitative data, the large differences in the abundance of species of small individual body
24 size require data transformations aimed at the reduction of excessive weight of the most abundant species. Factorial
25 analyses have also been employed in the analysis of zooplankton series, but in this case the objectives were generally
26 related to the identification of the main species characterizing the series or as a reference space for projection of
27 environmental factors influencing copepod species. Valdés (1993) employed correspondence analysis to identify the
28 spatial and temporal structure of zooplankton samples from A Coruña and to infer the underlying oceanographic factors
29 affecting their distribution. Similarly, Cabal (1993) applied principal component analysis to copepod abundance records
30 in the Mar Cantábrico to the identification of the main patterns of variability across the shelf and through the seasonal

1 succession. Further application of factorial analysis was the use of three-mode principal components analysis to address
2 simultaneously spatial, temporal and species variability in plankton time-series (Beaugrand et al., 2000). Factorial
3 analysis, however, have relatively strong restrictions in their application to biological counts, as normality,
4 homoscedascity and proportionality between the number of variables and observations (Digby and Kempton, 1987). In
5 contrast, MDS ordination, even when it is also dependent on the data transformations and similarity measures chosen, it
6 makes few assumptions about the distribution of the data or the inter-relationship of the observations, and its rationale is
7 the preservation of these relationships in the low-dimensional ordination space (Clarke and Warwick, 2001). The
8 resulting ordination retains fundamental characteristics of the original data, as shown by the correspondence between
9 the observations plotted in Fig. 2 and their geographical location in Fig. 1. In addition, the use of biomass data in our
10 study allowed for an ordination of species related to their actual contribution to biomass and fluxes in the pelagic food
11 web.

12 4.2. Regional vs. local variability

13 Previous studies in this region showed that seasonality was one main source of variability in copepod abundance
14 (Valdés, 1993; Cabal, 1993, Valdés and Moral, 1998; Valdés et al., 2007). Our results also point to the importance of
15 seasonal variability but mainly in the biomass of main species and total biomass, reaching up to 30% of total variance.
16 Even in this case, significance of seasonality was more common in copepod series from the north and east of the study
17 area (A Coruña and Santander) than in the eastern and south series (Vigo and CPR). These results reflect the important
18 role of the upwelling in the west of the area, disturbing the expected seasonal cycle imposed by the thermal
19 stratification of the water column, as described for the Mar Cantábrico (Cabal, 1993; Villate et al., 1997; Valdés and
20 Moral, 1998). In contrast, diversity and species richness did not show significant seasonality in any of the series,
21 suggesting that copepod species assemblages were approximately constant through the region. Changes in diversity
22 were therefore related to the annual succession and to the disturbance introduced by occasional upwelling events
23 (Valdés, 1993).

24 Local variability in the patterns of water column stratification was the main differential factor among series. Previous
25 studies also noted the different patterns of thermal stratification in the coastal series of this region (Valdés and Moral,
26 1998; Valdés et al., 2007). The use of σ_t differences instead of the variability in the vertical profiles of temperature in
27 this study, however, allowed for a better characterization of the water column of all series, as in those from Galicia
28 salinity variability due to the influence of nearby rias and runoff was larger than in the Mar Cantábrico (Varela et al.,
29 2005), where thermal stratification prevailed (Botas et al., 1989; González-Pola et al., 2007). For instance, copepods

1 from Galicia are exposed to larger variability in stratification than those from the Mar Cantábrico. Stratification largely
2 controls the input of nutrients into the upper photic layers and thus influences the structure and function of pelagic food
3 webs. The intensity and duration of the stratification phase is expected to increase as a result of global warming
4 (Roemmich and McGowan, 1995; Sarmiento et al., 2004), as observed in the Mar Cantábrico (Valdés et al., 2007).
5 Decreasing upwelling intensity and frequency off the western Iberian peninsula in the last 40 y (Lemos and Sanso,
6 2006; Alvarez et al., 2008) may have contributed to enhance stratification but the observed series in Galicia did not
7 show significant year-to-year variability. Changes in the salinity of upwelled waters (Pérez et al., 2000) and the
8 influence of freshwater along the coast (Varela et al., 2005), however, ensure a large variability of stratification in
9 Galicia. Our results confirm that the higher biomass and abundance of the main species in Galicia compared to those in
10 the Mar Cantábrico series are related to the frequent disturbance introduced by upwelling and other events affecting
11 stratification (Valdés, 1993; Valdés et al., 2007; Bode et al., 2009), even during a multidecadal period of decreasing
12 upwelling. However, the effect appears to depend largely on the frequency of the disturbance (as increasing density
13 gradients significantly decreased copepod biomass in Galicia but not in Santander; Table 5) rather than on the mean
14 value of the stratification measure chosen (as found with the standard deviation of temperature in Valdés et al., 2007).
15 Our comparative analysis of the series at intraseasonal time scales reveals a general coincidence in the environmental
16 forcing factors identified with those of annual scale studies in this region (Beaugrand et al., 2000; 2002; Valdés et al.,
17 2007; Bode et al., 2009). Warming of the surface waters allows for increasing dominance of some species (as *T.*
18 *stylifera*) and contributes for substantial modifications in the stability of the water column, particularly in the Bay of
19 Biscay. The upwelling and outflow from the rias in Galicia, however, modifies the direct influence warming and the
20 environmental fluctuations are mostly absorbed at annual scales (Bode et al., 2009). Therefore, temperature is generally
21 more influential on copepod communities in Santander than in Galicia, where upwelling intensity is the variable with
22 more significant cross-correlations (Table 5). Upwelling is also of marginal importance in the ocean, as shown by CPR
23 series. Nevertheless, large offshore advection could have been the cause of the decrease in diversity and total and *C.*
24 *helgolandicus* biomass in the period 1960-1986, characterised by the highest intensity and frequency of upwelling
25 (Lemos and Sanso, 2006). Furthermore, our analysis shows that the responses of zooplankton to environmental forcing
26 were lagged for several months. The delay between environmental change and changes in the community is indicative
27 of non-linear interactions, likely amplified through the food web (Duarte et al., 1990).
28 The different responses of the main copepod species to the environment can be related to their niche preferences. For
29 instance, the biomass of *Clausocalanus* spp. showed a positive relationship with warming and stratification of surface
30 waters in all coastal locations, as was noted in previous studies in a larger north Atlantic region (Beaugrand et al.,

1 2002). In contrast, *A. clausi* was more influenced by the intensity of upwelling and the presence of cold waters in the
2 surface, as this species is typical of upwelling-influenced, coastal sites in the southern Bay of Biscay (Alvarez-Ossorio,
3 1977; Corral and Alvarez-Ossorio, 1978; Valdés, 1993) but less dominant towards the west of the region, in the Mar
4 Cantábrico area (Villate et al., 1997; Valdés and Moral, 1998). Other species, however, showed different links to
5 environmental variables in Galicia compared to the Mar Cantábrico. For instance, *C. helgolandicus* showed a good
6 correspondence with increasing surface temperature at various time scales in the Mar Cantábrico, as noted in previous
7 studies (Cabal, 1993; Villate et al., 1997; Valdés and Moral, 1998), while it was positively related to cold waters and
8 upwelling in Galicia. According to recent reviews (Bonnet et al., 2005) this species is generally found in waters with a
9 range of temperature from 9–20 °C, with maximum abundances from 13–17 °C. Therefore, water column conditions in
10 Galicia are within the optimal range for this species, whereas increasing warm-up of waters in the Mar Cantábrico may
11 drive it towards northern and colder areas.

12 **5. Conclusions**

13 Despite the marked transitional character imposed by the seasonal upwelling in the coast and nearby ocean of
14 northwestern Spain, the composition of copepod community is fairly consistent in this region. Species richness and
15 diversity in the analysed series vary within relatively narrow limits, even taking into account that some of the series
16 extend over more than 40 years. Structural differences, however, characterize each location. For instance, samples from
17 the nearby ocean show the largest variability because this series includes larger spatial and temporal scales than the
18 coastal ones, but also to the lack of copepod species of small body size as *P. parvus*, *O. plumifera* and *O. media*. Near
19 the coast, differences in the relative contributions to biomass by several dominant species explain most of the local
20 variability. *Acartia* species (mainly *A. clausi*) and *C. helgolandicus* are the species reaching highest average abundance
21 at almost all sites, but *P. parvus* contributes to the local differentiation of A Coruña series and *Clausocalanus* spp. to
22 that of Santander.

23 Year-to-year changes are largely dependent on the location and the period analysed. The number of copepod species,
24 *Clausocalanus* spp. and total biomass has been decreasing in A Coruña since 1994. *Calanus helgolandicus* also
25 decreased in Santander between 1991 and 2001. In Vigo, however, *A. clausi* and *C. helgolandicus* increased recently,
26 and the CPR series showed an increasing trend of biomass and species number in the period 1960-1986. For all series,
27 total copepod biomass follows the characteristic seasonal pattern related to the cycles of upwelling and local
28 oceanographic conditions, but seasonality in species cycles is more variable. The effect of regional (upwelling) factors
29 is modulated by local conditions (surface temperature and stratification) and significant lags in the response of

1 copepods occur at the intraseasonal scale (1 to 5 months). Upwelling can be associated to increases in copepod biomass
2 and diversity near the coast, particularly in A Coruña and Santander but decreases diversity, species richness and *C.*
3 *helgolandicus* in the nearby ocean. Warming of the surface waters also allows high biomass, diversity and species
4 numbers in the area of large influence of upwelling (Galicia) while in Santander it causes an immediate increase in
5 warm-tolerant species as *Clausocalanus* spp. and *C. helgolandicus* and a decrease in species related to cold, upwelling
6 waters, as *A. clausi*. These results highlight the importance of local factors in the response of plankton communities to
7 large scale variability in environmental conditions. Therefore, a few indicator species may be used to characterise
8 community changes at both local and regional scales as a result of environmental and climatic variability.

9 **Acknowledgements**

10 We are grateful to all scientists and technicians involved in plankton data collection and sustaining the time-series
11 employed in this study. D. Johns (SAHFOS) kindly provided the grid-averaged data from the CPR survey. G. González-
12 Nuevo and E. Nogueira (IEO, Centro Oceanográfico de Gijón) made available the software for the time-series analysis.
13 This research was funded in part by projects Radiales (IEO) and REFORZA (PGIDIT06RMA60401PR) of the Galician
14 Government (Xunta de Galicia).

5 ^a *Acartia* spp. and *A. longispina* (CPRF4); includes juvenile stages (VIE3, COE2)

6 ^b includes juvenile stages (VIE3)

7 ^c includes juvenile stages (COE2)

8 ^d includes juvenile stages (VIE3, COE2, SAE4)

1 Table 3.

2 Copepod species most characteristic of each series.

3

species	CPRF4		VIE3		COE2		SAE4	
	S_m/S_{sd}	%S	S_m/S_{sd}	%S	S_m/S_{sd}	%S	S_m/S_{sd}	%S
<i>A. clausi</i>	1.2	23.0	2.9	14.2	3.0	12.9	2.1	7.9
<i>C. helgolandicus</i> (I-IV)	0.7	7.9	2.5	12.2	1.8	7.0	---	---
<i>C. helgolandicus</i> (V-VI)	1.2	12.1	---	---	1.2	5.5	2.4	10.8
<i>Clausocalanus</i> spp.	0.7	8.9	---	---	1.6	7.4	3.8	12.8
<i>P. parvus</i>	---	---	3.4	9.3	3.4	9.0	5.5	12.9

4

5 %S: percent contribution of each species to total within series Bray-Curtis similarity

6 S_m/S_{sd} : ratio between the mean and the standard deviation of similarity for each species

1
2
3

Table 4. Significant ($P < 0.05$) parameters of the Box-Jenkins model decomposing copepod time-series variance. The model equation is in the form: $X_t = M + b X_t + A \cos [(2\pi/T) t + P] + F X_{t-lag} + R_X$. X : dependent variable. R_X : prewhitened residuals. t : time (months). Name of series as in Table 1.

- 1 M: mean, b: slope of the linear regression with time (trend), T: period (months), A: amplitude, P: phase, F: autoregressive parameter, lag_{AR} : autoregressive lag, $\%V_i$: variance
- 2 contribution (percent) of each component, $\%V_M$: total variance contribution of the model, n: number of data points.
- 3 S: copepod species number, B: copepod biomass, H: copepod diversity.

1 Table 5. Significant ($P < 0.05$) cross-correlation coefficients between environmental (env) and copepod (cop)
 2 variables after removal of linear, periodic and autocorrelation components.
