**Abstract.** The surface signature of Agulhas rings propagating across the South Atlantic Ocean is observed based on three independent data sets: Advanced Microwave Scanning Radiometer for the Earth Observing System/Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI) (TMI/AMSR-E) satellite sea surface temperature, Argo profiling floats and a merged winds product derived from scatterometer observations and reanalysis results. A persistent pattern of cold (negative) sea surface temperature (SST) anomalies in the eddy core, with warm (positive) anomalies at the boundary, is revealed. This pattern contrasts with the classical idea of a warm core anticyclone. Taking advantage of a moving reference frame corresponding to the altimetry-detected Agulhas rings, modifications of the surface winds by the ocean-induced currents and SST gradients are evaluated using satellite SST and wind observations. As obtained, the averaged stationary thermal expression and mean eddy-induced circulation are coupled to the marine atmospheric boundary layer, leading to surface wind anomalies. Consequently, an average Ekman pumping associated with these mean surface wind variations consistently emerges. This average Ekman pumping is found to explain very well the SST anomaly signatures of the detected Agulhas rings. Particularly, this mechanism seems to be the key factor determining that these anticyclonic eddies exhibit stationary imprints of cold SST anomalies near their core centers. A residual phase with the maximum sea surface height (SSH) anomaly and wind speed anomaly is found to the right of the mean wind direction, apparently maintaining a coherent stationary thermal expression coupled to the marine atmospheric boundary layer.

## 1 Introduction

The Agulhas rings are important features of the South Atlantic circulation, with particular relevance for the great ocean conveyor belt. It is believed that virtually all the upper layer overturning circulation in the Atlantic originates from Indian Ocean leakage through Agulhas rings. Although previous studies have estimated the Agulhas rings general characteristics and pathways in the South Atlantic (e.g., Dencausse et al., 2010; Souza et al., 2011a), these do not usually include their thermal signature on the surface. Moreover, studies that have observed the Agulhas rings at sea (e.g., van Aken et al., 2003) are usually restricted to newly formed eddies and do not represent their modifications along their lifetimes. The eddy surface thermal signatures and their evolution over time have important consequences on the air–sea fluxes, impacting the overlying marine atmospheric boundary layer (MABL) with possible consequences on the regional atmospheric circulation.

As now available, long-term observations of concurrent satellite measurements of sea surface height (SSH), sea surface temperature (SST), and scatterometer surface vector winds enable detailed studies of the ocean–atmosphere coupling (e.g., Chelton et al., 2011; Siegel et al., 2011). High-resolution SSH fields obtained by merging measurements from several operating satellite altimeters help detect and track coherent rotating mesoscale ocean structures and better quantify their dynamics. As has been reported (e.g., Kudryavtsev et al., 2005), the near-surface wind field adjustment to SST changes across oceanic eddies occurs within an internal boundary layer developing on the downwind side of

the sea front. Statistically, observed SST-induced perturbations on the surface wind stress or the scatterometer wind curl and divergence fields have been found to be linearly well correlated with small scale perturbations in the crosswind and downwind SST gradients, respectively (e.g., Chelton et al., 2001, 2007; O'Neill et al., 2005, 2010). Moreover, important consequences on cloud fraction and water content of the MABL, and a reduction in rainfall have been observed for cyclones in the Southern Ocean by Frenger et al. (2013).

Considering these ocean–atmosphere interactions, Businger and Shaw (1984, see the schematic diagram in their Fig. 10) earlier sketched several interactions of eddy SST imprints with the atmospheric boundary layer, and numerous studies have clearly evidenced air–sea couplings over oceanic mesoscale coherent structures (e.g., Chelton et al., 2001, 2007; Small et al., 2008). As summarized in Small et al. (2008), the main coupling mechanisms are related to (i) changes in the near-surface stability and surface stress, (ii) vertical transfer of momentum from higher atmospheric levels to the surface due to an increase of the turbulence in the boundary layer, (iii) secondary circulations associated with perturbations in the surface atmospheric pressure over the SST fronts and (iv) the impact of the oceanic eddy currents on the net momentum transferred between the atmosphere and the ocean.

The objective of this study is to characterize the surface thermal signature of Agulhas rings propagating across the South Atlantic Ocean and the associated wind perturbation. An air–sea coupling mechanism over the oceanic mesoscale eddies emerges from the relationship observed between the wind and SST patterns.

To analyze the air–sea coupling over Agulhas rings, the present work takes advantage of a moving reference frame (Lagrangian) corresponding to altimetry-detected mesoscale Agulhas rings propagating in the South Atlantic basin. This approach permits the evaluation of the eddy-tracked average modifications to surface winds by the sea surface temperature (SST) gradients, using satellite SST and wind observations. Agulhas rings are the largest mesoscale eddies in the world, with large radii ( $165 \pm 69$  km) and durations ( $497 \pm 233$  days) (see Souza et al., 2011a). Accordingly, the Lagrangian approach can easily be implemented to reveal the persistent structures of SSH, SST and wind anomalies using standard medium-resolution satellite products, as presented in Sects. 2 and 3. Our study follows earlier investigations on the modification of the surface winds over Gulf Stream rings (Park et al., 2006), but benefit from the higher temporal sampling of surface wind and SST information over isolated altimetry-detected rings.

Three independent data sets – TMI/AMSR-E SST satellite observations, Argo profiling floats and a merged wind product derived from scatterometer measurements and a reanalysis – are used to describe the imprint of Agulhas rings on the SST field in Sect. 4. The evidence of the mean air–sea coupling over the detected rings is presented in Sect. 5, clearly

exhibiting the mean eddy/wind interactions. Maintaining the expectation that stationary thermal expression and relative air–water velocity are well expressed in the near-surface marine atmospheric boundary layer, the corresponding average Ekman pumping associated with the mean surface wind variations can then be evaluated. As revealed, the persistent eddy-induced Ekman pumping compares very well with the observed SST anomalies, as discussed in Sect. 6. Conclusions derived from the present analysis follow in Sect. 7.

## 2 Data

For our purposes, wind information from a blend of Quick Scatterometer (QuikSCAT) observations and reanalysis results, gridded SSH from Archiving, Validation and Interpretation of Satellite Oceanographic (AVISO) data, blended TMI/AMSR-E SST over a four-year period (between January 2005 and December 2008) and Argo float temperature profiles are used.

### 2.1 Blended wind fields

The blended wind product used in the present study is available for download in NetDCF format at (<ftp://ftp.ifremer.fr/ifremer/cersat/products/gridded/psi-concentration/>), and a complete description is provided by Bentamy et al. (2007). To enhance the spatial and temporal resolutions ( $0.25^\circ$  at synoptic times 00:00, 06:00, 12:00 and 18:00 UTC), a method has been implemented to blend the remotely sensed wind observations derived by the satellite QuikSCAT scatterometer and by three Special Sensor Microwave Imagers (SSM/I) on board Defense Meteorological Satellite Program (DMSP) satellites F13, F14 and F15 with the European Centre for Medium-Range Weather Forecasts (ECMWF) analyses. This provides a uninterrupted, high-resolution ( $\sim 25$  km) data set of wind velocities over the eddy tracks during the analyzed period.

### 2.2 AVISO SSH data

Four years of SSH data from the AVISO reference product were used to identify and track the Agulhas rings. It corresponds to a merged satellite product, projected on a  $1/3^\circ$  horizontal resolution Mercator grid, in time intervals of 7 days. Sea level anomalies (SLA) were obtained by subtracting the temporal mean SSH (2006–2009) from each grid point. A low-pass Hanning filter with a window of 175 days was used to remove seasonal and inter annual signals. Since the focus of the present study is on the mesoscale oceanic eddies, a Lanczos filter was applied to eliminate variability with length scales larger than 1000 km.

### 2.3 TMI/AMSR-E SST fields

An optimally interpolated SST (OI-SST) product, combining TRMM Microwave Imager (TMI) and Advanced Microwave Scanning Radiometer for EOS (AMSR-E) data sets, is used to provide the SST over the Agulhas rings. This product provides daily “cloud free” SST maps, with approximately 25 km spatial resolution – compatible with the wind data set. The data can be downloaded and details about the optimal interpolation procedural can be found at [www.remss.com](http://www.remss.com). This data set is produced by Remote Sensing Systems and is sponsored by the National Oceanographic Partnership Program (NOPP), the NASA Earth Science Physical Oceanography Program and the NASA Measures Discover Project.

### 2.4 Argo profiling floats

Argo is a global ocean observing system for the 21st century ([www.argo.net](http://www.argo.net)) composed of approximately 3000 profiling floats, used to create  $3^\circ \times 3^\circ \times 10$ -day resolution array between  $60^\circ$  S to  $60^\circ$  N. These autonomous floats measure temperature and salinity down to 2000 m depth, every 10 days. A complete description of the Argo program and access to the data can be obtained at <http://www.ARGOUcsd.edu/>. In the present study, we take advantage of the Argo profiles collocated with the Agulhas rings in space and time, and a derived mean vertical temperature anomaly structure, derived by Souza et al. (2011b).

## 3 Methods

The present work takes advantage of a Lagrangian point of view along the eddy tracks to quantify the anomalies in the surface variables (SSH, SST and wind) over the large mesoscale Agulhas rings propagating in the South Atlantic basin.

### 3.1 Eddy identification and tracking algorithm

An automated method based on the SLA (Chaigneau et al., 2009) was used to identify and track the Agulhas rings. The eddy identification process is performed at each time step, or SLA map, through two stages: (1) the identification of local SLA modulus maxima corresponding to the eddy centers and (2) the selection of closed SLA contours associated with each eddy center. The outermost contour embedding only one center is considered as the eddy edge. This method is similar to the one applied by Chelton et al. (2011), and showed improved results and performance in terms of processing time when compared to other classical methods (Souza et al., 2011a).

A total of 16 Agulhas rings with durations larger than six months were identified. The results from the tracking algorithm together with the general ring characteristics are discussed by Souza et al. (2011a). A good agreement with

previous work was achieved, with “typical” Agulhas rings shed every 2–3 months and with a diameter of 150–200 km (van Sebille et al., 2010; van Aken et al., 2003). It is important to emphasize that due to the “noisy” SSH in the Agulhas Current retroflexion region, the automated method does not identify the structures in the exact moment of their formation. Therefore, the derived SST and wind anomaly signatures correspond to Agulhas rings propagating in the South Atlantic interior after leaving their formation region. This is important since the SST signature of newly formed Agulhas rings is in fact warm (e.g., Gladyshev et al., 2008; Arhan et al., 2011). However, when the structures propagate northwestward into the warmer South Atlantic basin their SST anomalies in relation to the surrounding waters become cold, as revealed in the next section.

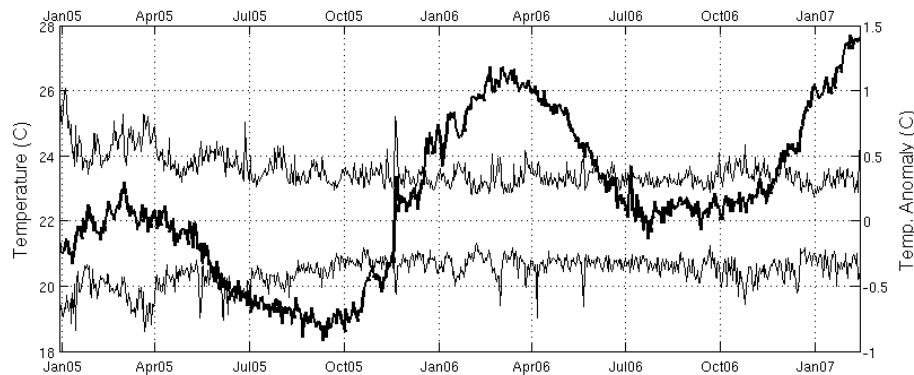

### 3.2 Data cropping and spatial high-pass filtering

The SST anomaly ( $T'$ ) and SST-driven wind speed variability, or wind anomaly ( $V'$ ), were isolated by removing the large spatial scale variability using a “loess” smoothing function with half-power filter cutoffs of  $5^\circ$  latitude by  $5^\circ$  longitude. The cutoff wavelengths were chosen to better isolate the influence of the mesoscale eddies from the mean field and larger-scale processes, such as propagating Rossby waves. After the eddy identification and tracking processes, the ring positions are linearly interpolated from the 7-day SLA derived axis to daily positions compatible with the SST and wind data sets. For the comparison between wind and SST, these data sets were linearly interpolated to a 25 km resolution grid in a region of 700 km (north–south and west–east) centered over the eddy core position at each time are determined from the altimetry. The properties were then projected on a horizontal grid normalized by the eddy diameter at each time step. That way, the obtained spatial patterns are isolated from the variability of the eddy diameters between distinct structures and over time.

The mean wind direction over each ring at each moment was calculated and used as a reference. For the comparison between the wind and SST, all data fields were rotated to have the  $x$  axis oriented to the mean wind at each time. Cross-wind and downwind SST gradients ( $(\partial T/\partial c)'$  and  $(\partial T/\partial d)'$ , respectively) and the wind divergence and vorticity ( $(\nabla \cdot \mathbf{u})'$  and  $(\nabla \times \mathbf{u})'$ , respectively) were calculated at each grid point following the method described by O'Neill et al. (2010).

## 4 Surface thermal signature of the Agulhas rings

The Agulhas rings are strong anticyclonic mesoscale eddies, referred to as the largest mesoscale eddies in the world by Bistoch et al. (2008). They play an important role in the transport of Indian Ocean waters to the South Atlantic. These anticyclones are usually associated with warm (positive)  $T'$  in their formation region, near the Agulhas Current retroflexion

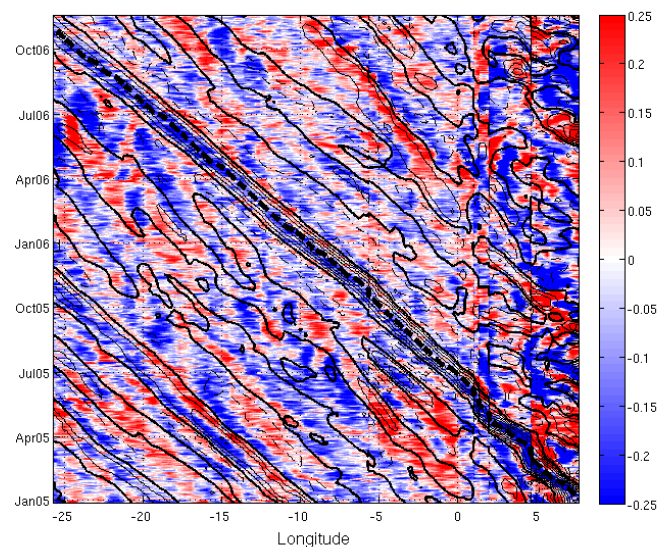

**Figure 1.** Time series of the maximum (warm) and minimum (cold)  $T'$  inside the eddy (thin lines) and absolute SST at the eddy center (thick line) for an Agulhas ring tracked between January 2005 and February 2007.

in the southern tip of the African continent (e.g., Arhan et al., 2011; Schmid et al., 2003; Garzoli et al., 1999). As an example, Arhan et al. (2011) and Gladyshev et al. (2008) observed anticyclonic eddies with core temperatures between 11.8 °C and 12.5 °C approximately at 43–40° S embedded in climatological SSTs lower than 10 °C.

But when these rings leave their formation region and move to lower latitude warmer waters, the positive signature on the  $T'$  becomes less clear. Moreover, although the waters present in the eddy cores are trapped and relatively laterally isolated from the surrounding ocean (Souza et al., 2011b), fluxes in the air–sea interface and the base of the mixed layer are expected to act modifying the upper layer temperature.

Taking as an example an Agulhas ring tracked between December 2004 and February 2007, it is possible to observe in Fig. 1 that while the absolute SST at the eddy center (determined from the SLA) present a seasonal cycle with a warm trend as the ring propagates northwestward, cold and warm signatures in  $T'$  are present inside the eddy and decrease together over time without a clear seasonal influence. This is similar to the behavior observed for the SLA at the eddy core by Souza et al. (2011a). While these authors obtained a decrease rate of  $9.33 \times 10^{-5} \text{ m day}^{-1}$  for the SLA, a linear fit to the  $T'$  modulus results in an amplitude decrease rate of  $3.1 \times 10^{-4} \text{ °C day}^{-1}$ . Observing the anomaly curves in Fig. 1, one can see that this decrease is, in fact, faster in the early days of the eddy lifetime and becomes smoother after the first year. The absolute values for  $T'$  are typically lower than 0.5 °C after the first year of the eddy formation. This makes it difficult to track the eddy signature in SST satellite images, especially when it approaches the warm waters of the Brazil Current.

The  $T'$  present similar magnitude cold and warm values inside the ring core that stay in phase during the eddy lifetime. However, in contrast to the warm core observed near the formation region by Arhan et al. (2011), the Hovmoller diagram of Fig. 2 reveals a persistent cold (negative)  $T'$  at

**Figure 2.** Hovmoller diagram of the SLA and SST anomaly ( $T'$ ) along the trajectory of an Agulhas ring first observed on 24 January 2005. The colors correspond to the SST anomalies, while the black contours present the SLA with 0.1 m interval. The thick black lines are the zero SLA contours, while the thick black dashed line present the trajectory of the eddy center. It is possible to observe that the eddy core is generally associated with cold (negative) SST anomalies.

the eddy center identified from the altimetry, and warm (positive) anomalies near the eddy boundaries.

To analyze these anomalies taking into account all the 16 Agulhas rings identified in the present study, let us first define the eddy “thermal center” as the position of the maximum  $T'$  modulus closest to the SLA maximum. The time series of the mean  $T'$  at the eddy thermal centers (Fig. 3) show that these negative (cold) anomalies are persistent during observed period, with a mean value of approximately  $-0.56 \text{ °C}$ . The range presented by the thin gray lines in Fig. 3, with the maximum and minimum values of  $T'$  between the different

rings, indicate that all observed eddies presented persistent cold cores.

Such pattern of cold  $T'$  in the eddy core is also present in the mean Agulhas ring vertical structure calculated from the Argo float temperature profiles by Souza et al. (2011b) (Fig. 4) for the same 16 rings analyzed in the present work. Focusing on the top layer of the water column, the mean Argo temperature anomaly section shows an eddy core dominated by cold (negative)  $T'$  while the warm (positive)  $T'$  is shifted to the left (west) of the center. The warm anomaly occupies the eddy core with depth due to the tilt between the temperature and velocity anomaly vertical structures. Although the mean vertical structure obtained from the Argo floats is the product of a series of simplifications used to combine profiles from different stages of the eddy lives, and it is restricted to a zonal section, it agrees with the mean spatial pattern of the eddy surface thermal signature as obtained from the TMI/AMSR-E SST product (Fig. 5). This mean surface signature also shows a cold  $T'$  core with warm anomalies in the boundary, especially on the southern portion of the eddy. Although a large standard deviation (sd) is observed for  $T'$  this mean picture is robust, especially in the eddy core as shown by the ratio between the eddy averaged mean and sd of  $T'$  (see the Supplement). A similar distribution in the blended winds shows weaker (negative)  $V'$  close to the eddy center and stronger (positive)  $V'$  at the eddy boundary. Such a relationship between  $V'$  and  $T'$  has been previously observed by several authors (a review is provided by Small et al., 2008). Thus, the obtained distribution of  $V'$  reinforces the observed spatial pattern in  $T'$ . Moreover, it suggests that a coupling mechanism between the upper ocean and the MABL is responsible for sustaining the observed structures.

## 5 Evidence of air–sea coupling over the Agulhas rings

As averaged, the mean spatial patterns of  $V'$  and  $T'$ , Fig. 5, exhibit a correlation of 0.61 with an apparent phase shift. Simply shifting the wind field position in relation to the SST and recalculating the resulting correlations, a maximum value of 0.87 is obtained for a spatial shift on the order of one quarter of the ring radius ( $\sim 50$  km) to the right of the mean wind direction (downward). Since the Agulhas rings propagation region is dominated by the westerly winds, this is the same to say the wind is shifted equatorward (approximately  $0.5^\circ$ ) to the  $T'$  center. A spatial shift between the wind and the SST was already reported in previous studies. Considering four distinct regions (Kuroshio Current, Gulf Stream, Brazil–Malvinas confluence zone and the Agulhas Return Current), O'Neill et al. (2010) estimated a mean shift of  $1^\circ$  ( $\sim 110$  km). In our case, two processes contribute to the air–sea coupling over the rings: (a) the wind accelerates (decelerates), with slight changes in wind direction, over warm (cold) SST anomalies and (b) the impact of the oceanic eddy velocities on the relative air–water velocity on diametrically

opposite sides of the eddies systematically act to modify the wind field.

Indeed, the spatial pattern for the wind perturbations in Fig. 5 suggests an influence of the oceanic eddy velocities, reducing (augmenting) the wind in the upper (lower) part of the ring. It is important here to remember that the influence of the ocean currents was removed from the scatterometer winds prior to the analysis.

Accordingly, a coincidence in the spatial patterns of  $(\nabla \cdot \mathbf{u})'$  and  $(\partial T / \partial d)'$  is expected and observed, Fig. 6a. Taking into account the same spatial shift observed between  $V'$  and  $T'$ , the correlation changes from 0.29 to 0.83. For the relationship between  $(\nabla \times \mathbf{u})'$  and  $(\partial T / \partial c)'$  (Fig. 6b), a shift of 25 km (1 grid cell) enhances the anti-correlation from  $-0.39$  to  $-0.67$ . However, the present results are statistically robust and favor the dominant effect of the eddy-induced circulation to explain both the weaker correlation between  $(\nabla \times \mathbf{u})'$  and  $(\partial T / \partial c)'$ , and the very large linear regression coefficient between  $(\partial T / \partial d)'$  and shifted  $(\nabla \cdot \mathbf{u})'$ , as discussed in the next section.

### 5.1 Linear relationship between the wind and the SST

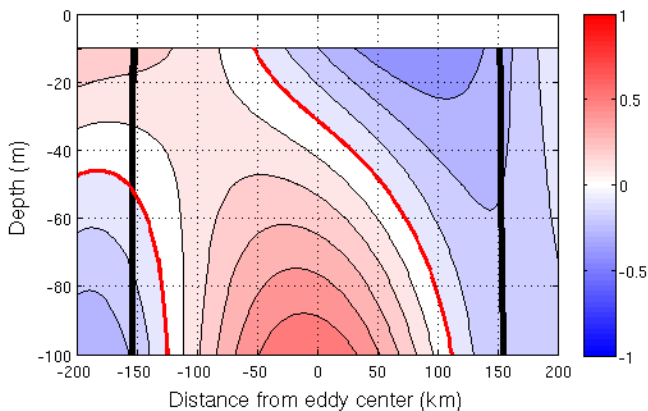

Linear relationship between the wind stress curl and divergence, and the crosswind and downwind SST gradients were originally observed by Chelton et al. (2001) over energetic regions of the world ocean, where strong and persistent SST fronts are present. However, it is still not clear if the same relationships hold for the less energetic ocean interior, with the sporadic occurrence of eddies. This is the case of the Agulhas rings that propagate across the South Atlantic interior. Following this idea, linear fits between the binned properties were obtained and their respective slopes calculated. To investigate the relationship between the wind and SST, the wind properties  $V'$ ,  $(\nabla \times \mathbf{u})'$  and  $(\nabla \cdot \mathbf{u})'$  were binned in function of  $T'$ ,  $(\partial T / \partial c)'$  and  $(\partial T / \partial d)'$ , respectively. All the data including the complete time span of all 16 identified Agulhas rings were used, without spatial shift correction.

The linear relationship between  $T'$  and  $V'$  in Fig. 7 shows a similar slope (0.31) as the relationship observed for the Gulf Stream region (0.27) by O'Neill et al. (2010). The  $T'$  values are concentrated in the range  $\pm 1^\circ\text{C}$ , corresponding to perturbations in  $V'$  of  $\pm 0.6\text{ m s}^{-1}$ . These values are smaller than observed by previous authors, reflecting the fact these rings represent a weaker perturbation in the SST field when compared to western boundary current frontal systems. But the comparable values of the slopes indicate a similar coupling between the SST and the wind speed over the structures, suggesting the same mechanisms are dominant.

The linear fits between  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  and  $(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$  in Fig. 8 showed stronger slopes (1.47 and  $-1.26$ ) than observed by previous authors. O'Neill et al. (2010) obtained slope values between 0.44 and 0.73 for  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  and between  $-0.21$  and  $-0.45$  for  $(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$ . This indicates stronger coupling between the wind

**Figure 3.** Time series of the mean  $T'$  in the eddy thermal centers (thick line) showing the persistence of negative (cold) values. The thin gray lines indicate the maximum and minimum values of  $T'$  at the eddy thermal centers between the different rings identified at each time, showing that all observed structures presented cold cores.

**Figure 4.** Top 100 m of the Agulhas rings mean  $T'$  vertical structure (c.i.  $0.1^\circ\text{C}$ ) obtained from the Argo float vertical profiles by Souza et al. (2011b) (c.i.: contour interval). The red contours indicate the  $0^\circ\text{C}$   $T'$ , while the thick black lines delimit the water trapped region following the criteria by Flierl (1981). The cold (negative)  $T'$  dominates the eddy core near the surface, while the warm (positive)  $T'$  is shifted to the left (west).

and the SST gradients over the Agulhas rings. In particular, the case of the  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  shows a high slope, which means the wind convergence presents a strong response to the SST structure. The observed differences in the linear fit slope indicate that characteristics other than the SST may be influencing the MABL winds. Aspects such as the mean atmospheric circulation and latitude impact the air–sea coupling and are analyzed in the next section.

## 5.2 Mean characteristics influencing the coupling

Several physical mechanisms influence the air–sea coupling over oceanic mesoscale structures. Small et al. (2008) propose as main processes the modification of the near-surface stability, the mixing of momentum, heat and humidity from higher levels into the MABL due to the increased turbulence, the formation of secondary circulation cells related to

**Figure 5.** Map of the mean perturbation wind speed ( $V'$  color contours) and  $T'$  (black contours – c.i.  $0.01^\circ\text{C}$ ) obtained from the 16 Agulhas rings observed between January 2005 and December 2008. The thick black line represents the  $0^\circ\text{C}$   $T'$ , the continuous lines positive values and the dashed lines negative values of  $T'$ . The figures' axes represent the distances from the eddy centers normalized by the eddy diameters.

perturbations in the pressure field and the impact of oceanic eddy velocities on the surface shear. Diverse environmental properties influence these mechanisms, altering their relative balance over the eddies.

Using the differences between the environmental conditions influencing the 16 Agulhas rings identified in the present study it is possible to investigate the importance of the environmental properties on the coupling. To achieve this, the correlations and slopes between  $V' \times T'$ ,  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  and  $(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$  of each ring were compared to their correspondent mean wind speed ( $V$ ), latitude, eddy diameter and amplitude. The results are shown in Table 1, where the correlations statistically relevant to the 95 % level are emphasized. It is observed that the latitude is

**Figure 6.** (a)  $(\nabla \cdot \mathbf{u})'$  as color contours and  $(\partial T / \partial d)'$  as black contours – c.i.  $1 \times 10^{-7} \text{ }^\circ\text{C}$  per 100 km. (b)  $(\nabla \times \mathbf{u})'$  (color contours) and  $(\partial T / \partial c)'$  (black contours – c.i.  $1 \times 10^{-7} \text{ }^\circ\text{C}$  per 100 km). The thick black lines represent the  $0 \text{ }^\circ\text{C}$  per 100 km contours, the continuous lines positive values and the dashed lines negative values of  $T'$  gradient. The figures' axes represent the distances from the eddy centers normalized by the eddy diameters.

**Table 1.** Correlations between the slopes and correlation factors that indicate the air–sea coupling over the 16 Agulhas rings observed in the present study. The emphasized values correspond to the correlations statistically relevant to the 95 % level.

**Figure 7.** Binned scatter plots of the  $V'$  as function of  $T'$ . The bin averages were computed using all the data points from the 16 observed Agulhas rings. The points and error bars represent the mean within each bin and the standard deviation, and the lines are the linear fits. The histogram in the lower panel presents the relative distribution of the data between the bins.

**Figure 8.** Binned scatter plots of the  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  in red and  $(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$  in blue. The bin averages were computed using all the data points from the 16 observed Agulhas rings. The points and error bars represent the mean within each bin and the standard deviation, and the lines are the linear fits. The histogram in the lower panel presents the relative distribution of the data between the bins.

**Figure 9.** Correlations (a) and slopes (b) between  $T' \times V'$  as thick continuous lines,  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  as thin continuous lines and  $-(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$  as thin dash-dotted lines and the mean Latitude (thick dash-dotted line) for the 16 Agulhas rings identified in the present study. A remarkable anti-correlation of the correlations and slopes with the latitude is observed.

negatively correlated with both the slopes and correlations (Fig. 9), while the mean wind intensity is positively correlated (Fig. 10). Since in this case we want to explore the influence of the mean atmospheric circulation on the coupling, the mean wind is defined as the temporal mean over the eddies. The eddy diameters and amplitudes presented low correlations with the analyzed properties that are not statistically relevant.

The influence of the latitude on the coupling can be explained through its impact on the thermal wind balance over the rings. A “temperature island” effect occurs due to the modifications in the heat flux over the SST anomalies. This heat flux generates pressure gradients in the lower MABL that create secondary cells of circulation. Following the thermal wind equation ( $\mathbf{u}'_g = \nabla P / \rho f$ ), the magnitude of the geostrophic wind perturbation ( $\mathbf{u}'_g$ ) due to this pressure gradient ( $\nabla P$ ) is inversely proportional to the Coriolis factor ( $f$ ). Since  $f$  is larger in higher latitudes,  $\mathbf{u}'_g$  is smaller, that is, the pressure gradient mechanism is less effective. Chelton et al. (2004) also observed the influence of the latitude in the air–sea coupling and affirmed that the SST influence on the mean wind stress is mostly restricted to regions poleward of  $40^\circ$  of latitude and the tropics, though the authors associated this effect to the persistence of the SST fronts over time. In the present study, we show that such effects are observed in lower latitudes as well ( $\sim 30^\circ$  S) and transient fronts, which can also be interpreted from the results of O’Neill et al. (2010).

The influence of the wind velocity is associated with a different process. It promotes modifications in the near-surface stability or, in the case of the wind curl, generates vertical velocities in the ocean that impact the SST (Ekman pumping). While the first case is the subject of extensive research

(e.g., Kudryavtsev et al., 1996; Park and Cornillon, 2002; Liu et al., 2007; O’Neill, 2012) and will not be treated in the present work, the second process explains an important feedback mechanism from the MABL into the ocean and is discussed in the next section.

## 6 Induced Eddy–Ekman pumping

As statistically revealed, wind modifications, and consequently wind stress, could possibly enhance vertical velocities through an Ekman pumping mechanism in the ocean. This further impacts the resulting evolution of the SST field and again the surface stress. Such a coupled feedback has been less explored than the impacts of the SST gradients on the surface winds. Liu et al. (2007) discuss the feedback of the wind speed anomalies on the ocean in terms of modifications in the wind stress, impacting the surface currents. The authors argue that since the neutral wind vorticity anomalies are small compared to those of the ocean currents, the ocean should dominate the mesoscale coupling in the long term. The feedback on the SST is then presented as function of the modifications in the surface latent heat flux. The role of the surface heat fluxes was further emphasized by Haack et al. (2008). From another point of view, using an idealized ocean–atmosphere coupled model to study the shelf-break frontogenesis, Chen et al. (2003) showed a positive feedback mechanism that strengthens both the wind and the front. Their results indicate that although the latent heat flux appears to be important, it is not an essential coupling mechanism. Jin et al. (2009) used the empirical relationship between the wind and SST presented by Chelton et al. (2007), leading to a simple representation of the mesoscale ocean–atmosphere coupling in an idealized upwelling system where the SST-induced wind curl intensification strengthens the offshore upwelling through Ekman pumping.

Under the present analysis, a more direct estimation can be made. To quantify the mean eddy–wind interactions, an  $f$  plane approximation in the eddy-centered reference frame is considered to estimate the mean Ekman vertical velocities ( $\mathbf{w}_{\text{EK}}$ ), also taking into account the oceanic geostrophic eddy vorticity ( $\zeta$ ) changes obtained from the geostrophic velocities derived from the observed SLA in the rings area (e.g., Stern, 1965):

$$\mathbf{w}_{\text{EK}} = \frac{1}{\rho_0} \left( \underbrace{\frac{\nabla \times \boldsymbol{\tau}}{f + \zeta}}_{\text{term 1}} + \underbrace{\frac{\nabla \zeta}{(f + \zeta)^2} \times \boldsymbol{\tau}}_{\text{term 2}} \right), \quad (1)$$

where  $\rho_0$  is the averaged oceanic mixed layer density, obtained considering a mean salinity of 35 and the observed SST, and  $\boldsymbol{\tau}$  is the wind stress simply obtained from a bulk relationship:

$$\boldsymbol{\tau}_{x,y} = \rho_{\text{AIR}} C_D \mathbf{V} |\mathbf{V}|, \quad (2)$$

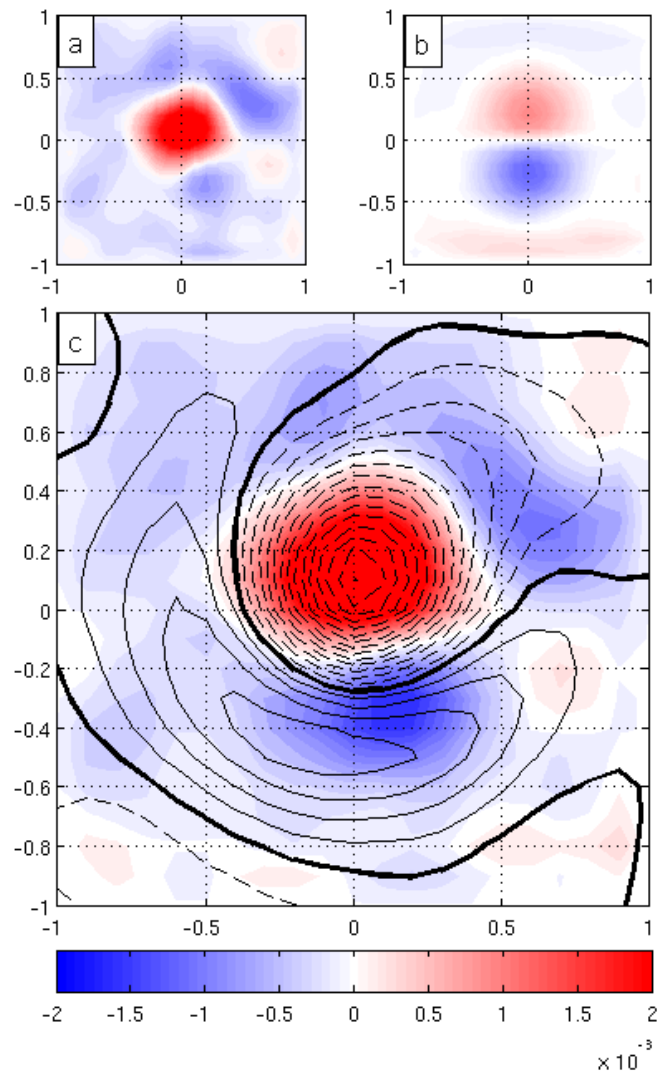

**Figure 10.** Correlations (a) and slopes (b) between  $T' \times V'$  (thick continuous line),  $(\nabla \cdot \mathbf{u})' \times (\partial T / \partial d)'$  (thin continuous line) and  $-(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$  (thin dash-dotted line) and the mean wind speed (thick dash-dotted line) for the 16 Agulhas rings identified in the present study. A remarkable concordance between the correlations and slopes with the wind speed is observed.

where  $\rho_{\text{AIR}}$  is the air density,  $C_D$  is the drag coefficient and  $V$  is the measured surface wind.  $C_D$  was calculated following Yelland and Taylor (1996). It is important to notice that for the Ekman pumping calculation the effect of the ocean currents on the observed scatterometer winds was not removed since the movement in relation to the ocean surface is the relevant quantity.

The two terms of  $w_{\text{EK}}$  in Eq. (1) take into account the particular contribution of the resulting wind stress curl, through the measured surface wind curl anomalies (term 1), and the oceanic vorticity divergence (term 2). As presented in Fig. 11,  $w_{\text{EK}}$  estimations overlay very well with the  $T'$  field.

The high correlation (0.9) between the two fields is illustrated in Fig. 12. The linear fit obtained between these two fields presents a  $-0.04$  slope. In this figure it is possible to observe that this linear relationship is strong in the region close to the eddy core, weakening with the distance from it. This means that this process holds only for the region under the influence of the eddy.

As clearly revealed, the Ekman pumping explains a persistent feedback mechanism linking the eddy-induced mean wind and SST anomalies on the Agulhas rings. Along their propagation in the South Atlantic basin, a residual persistent upward velocity acts to support a cooler temperature flux to sustain the mean observed cool anomalies in the core of the eddies. This mechanism is mostly driven by the observed resulting spatial changes in wind stress, but taking into account that the oceanic vorticity gradient improves the overall correlation between  $w_{\text{EK}}$  and  $T'$ , particularly contributing to the enhancement of the pumping asymmetry along cross-wind mean directions. As such, this observed asymmetry might lead to weaker SSH signatures, also impacting the ring propagation and attenuation (Dewar and Flierl, 1987). In fact, the

**Figure 11.** Results obtained for (a) term 1, (b) term 2 and (c) the total Ekman pumping velocity  $w_{\text{EK}}$  ( $\text{m day}^{-1}$ ) for the mean estimated Agulhas ring. A remarkable concordance is observed between the mean vertical velocities (color contours) and the observed mean  $T'$  (black contours – c.i.  $0.01^\circ\text{C}$ ). The  $w_{\text{EK}}$  is dominated by the  $(\nabla \times \boldsymbol{\tau})'$  (term 1), though the  $(\nabla \times \boldsymbol{\zeta})'$  (term 2) makes an important contribution. The figures' axes represent the distances from the eddy center normalized by the eddy diameters.

relative contribution of term 2 of Eq. (1) to the total  $w_{\text{EK}}$  displayed in Fig. 13 clearly shows that this term is responsible for up to 95% of the total vertical velocities in the lower (southern) portion of the ring. Considering the role of the mean eddy, term 2 accounts for, approximately, 30% of the total  $w_{\text{EK}}$ .

The feedback mechanisms through Ekman pumping have important consequences not only on the air–sea fluxes, but also on the primary productivity of the waters trapped inside the eddy. The present results support similar findings of the enhanced chlorophyll concentration inside an Agulhas ring

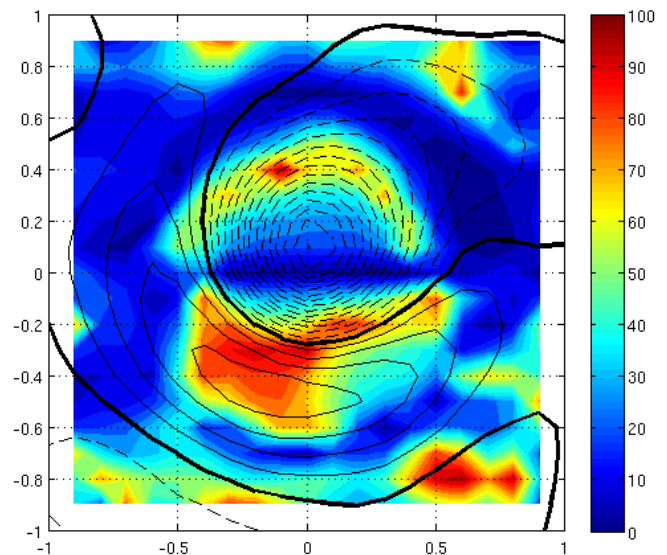

**Figure 12.** Relationship between the Ekman pumping vertical velocities ( $w_{EK}$ ) and  $T'$ . The color code represent the distance from the eddy center (km), showing that the linear relationship between these two fields is stronger closer to the eddy core, as demonstrated by the linear regression illustrated by the red line.

core as described by Lehahn et al. (2011), who observed a chlorophyll patch transported by an eddy along  $\sim 1500$  km in  $\sim 11$  months. Based on a ring first identified in April 2006, and using a particle transport model, these authors conclude that the water trapped inside the eddy core and changes in the mixed layer depth are responsible for the observed patches. The increase in the vertical mixing by particularly strong wind events is described as responsible for high frequency increments on the chlorophyll concentration. However, the present results revealed a persistent mean mechanism, sustaining positive  $w_{EK}$  at the eddy cores that are consistent with the observed high productivities. As showed in Fig. 10, the mean wind speed is in fact well correlated with both the slope and correlation of the  $(\nabla \times \mathbf{u})' \times (\partial T / \partial c)'$ , which explains the concordance between the chlorophyll concentration and the wind speed observed by Lehahn et al. (2011).

## 7 Conclusions

Using three independent data sets (TMI/AMSR-E SST fields, Argo profiling floats and a blended winds product), the present study reveals a particular surface thermal signature for the anticyclonic Agulhas rings as they propagate across the South Atlantic Ocean: cold  $T'$  in the eddy cores with warm anomalies at the boundaries. Consequently, in the interior of the South Atlantic basin the Agulhas rings are better described as  $T'$  dipoles, presenting strong positive and negative anomalies, than by the classical view of a warm core anticyclone that is consistent close to their formation region in the Cape Basin. These anomalies decrease in amplitude along the eddy tracks, but are still distinguishable during their whole lifetimes, estimated from the SLA.

A statistical analysis of the surface wind modifications over anticyclonic Agulhas rings is explored. The joint use of SSH, SST, and wind available products with improved

**Figure 13.** Relative contribution (%) of term 2 of Eq. (1) to the total Ekman pumping vertical velocity ( $w_{EK}$ ) in a mean Agulhas ring and the observed mean  $T'$  (black contours – c.i.  $0.01$  °C). It is possible to ascribe the particular importance of this term to the asymmetry of  $w_{EK}$  and  $T'$  with higher contributions (up to 95 %) in the lower (southern) part of the eddy.

spatiotemporal resolution helps to reveal persistent effects taking place over these long-lived large mesoscale rings. Impacts of their thermal and circulation surface signatures on the wind field were ascertained in the  $\mathbf{V}'$ ,  $(\nabla \cdot \mathbf{u})'$  and  $(\nabla \times \mathbf{u})'$  wind anomaly fields. The mean spatial patterns of  $\mathbf{V}'$  and  $T'$  show remarkable correlation, maximum value of 0.92, with a spatial shift on the order of one quarter of the ring radius to the right of the mean wind direction. Since the Agulhas rings propagate in a region dominated by the westerly winds, this is to say that the wind anomaly is shifted poleward (approximately  $0.5^\circ$ ) to the eddy thermal center.

A feedback mechanism explaining how the wind anomalies further influence the upper ocean thermal expression emerges. The wind stress curl  $(\nabla \times \boldsymbol{\tau})'$  and ring vorticity gradient  $(\nabla \times \boldsymbol{\zeta})'$  lead to an averaged Ekman pumping with a residual persistent upward velocity acting to support a cooler temperature flux at the oceanic mixed layer basis. This mechanism helps to sustain the mean observed cold anomalies and could be related to previous observations of high chlorophyll concentrations near the eddy cores. As revealed by the residual phase between the maximum SSH and cold SST anomalies, to the left of the mean wind direction, this residual Ekman pumping can affect the ring propagation and attenuation.
