### Abstract :

The available ecological and palaeoecological information for two sea ice-related marine diatoms (Bacillariophyceae), *Thalassiosira antarctica* Comber and *Porosira glacialis* (Grunow) Jorgensen, suggests that these two species have similar sea surface temperature (SST), sea surface salinity (SSS) and sea ice proximity preferences. From phytoplankton observations, both are described as summer or autumn bloom species, commonly found in low SST waters associated with sea ice, although rarely within the ice. Both species form resting spores (RS) as irradiance decreases, SST falls and SSS increases in response to freezing ice in autumn. Recent work analysing late Quaternary seasonally laminated diatom ooze from coastal Antarctic sites has revealed that sub-laminae dominated either by *T. antarctica* RS, or by *P. glacialis* RS, are nearly always deposited as the last sediment increment of the year, interpreted as representing autumn flux. In this study, we focus on sites from the East Antarctic margin and show that there is a spatial and temporal separation in whether *T. antarctica* RS or *P. glacialis* RS form the autumnal sub-laminae. For instance, in deglacial sediments from the Mertz Ninnis Trough (George V Coast) *P. glacialis* RS form the sub-laminae whereas in similar age sediments from Iceberg Alley (Mac.Robertson Shelf) *T. antarctica* RS dominate the autumn sub-lamina. In the Dumont d'Urville Trough (Adelie Land), mid-Holocene (Hypsithermal warm period) autumnal sub-laminae are dominated by *T. antarctica* RS whereas late Holocene (Neoglacial cool period) sub-laminae are dominated by *P. glacialis* RS. These observations from late Quaternary seasonally laminated sediments would appear to indicate that *P. glacialis* prefers slightly cooler ocean-climate conditions than *T. antarctica*. We test this relationship against

---

two down-core Holocene quantitative diatom abundance records from Dumont d'Urville Trough and Svenner Channel (Princess Elizabeth Land) and compare the results with SST and sea ice concentration results of an Antarctic and Southern Ocean Holocene climate simulation that used a coupled atmosphere-sea ice-vegetation model forced with orbital parameters and greenhouse gas concentrations. We find that abundance of *P. glacialis* RS is favoured by higher winter and spring sea ice concentrations and that a climatically-sensitive threshold exists between the abundance of *P. glacialis* RS and *T antarctica* RS in the sediments. An increase to  $>0.1$  for the ratio of *P. glacialis* RS:*T antarctica* RS indicates a change to increased winter sea ice concentration (to  $>80\%$  concentration), cooler spring seasons with increased sea ice, slightly warmer autumn seasons with less sea ice and a change from similar to 7.5 months annual sea ice cover at a site to much greater than 7.5 months. In the East Antarctic sediment record, an increase in the ratio from  $<0.1$  to above 0.1 occurs at the transition from the warmer Hypsithermal climate into the cooler Neoglacial climate (similar to 4 cal kyr) indicating that the ratio between these two diatoms has the potential to be used as a semiquantitative climate proxy.

**Keywords** : East Antarctica, Quaternary, diatoms, sea ice

## 71 1. Introduction

72

73 Most of the ecological and palaeoecological information available for sea ice-related marine  
74 diatoms *Thalassiosira antarctica* and *Porosira glacialis* suggests that these two species have  
75 similar sea surface temperature (SST), sea surface salinity (SSS) and sea ice proximity preferences  
76 and similar seasonal occurrences (summarised in Sections 1.1 and 1.2). For example, in Ross Sea  
77 surface waters that emerge from beneath the ice shelf, *T. antarctica* cells are associated with a  
78 diatom assemblage that also includes *P. glacialis* and *P. pseudodenticulata* (Cunningham and  
79 Leventer, 1998). Along the Mac.Robertson Shelf in Iceberg Alley (Figure 1) deglacial seasonally  
80 laminated sediments contain abundant *P. glacialis* resting spores (RS) that are found within *T.*  
81 *antarctica* RS-dominated sub-laminae that were deposited during autumn (Stickley et al., 2005).  
82 On the other hand, in Dumont d'Urville Trough, Adélie Land (Figure 1), sub-laminae dominated by  
83 *T. antarctica* RS are found in mid-Holocene (relatively warm, Hypsithermal) laminated sediments  
84 (Core MD03-2601, Denis et al., 2006), whereas sub-laminae dominated by *P. glacialis* RS are

85 found in late Holocene (cool, Neoglacial) sediments (Core MD03-2597, Maddison, 2006). Further,  
86 deglacial/early Holocene laminated sediment from Mertz Ninnis Trough, George V Coast (Figure  
87 1), also contain sub-laminae dominated by *P. glacialis* RS (Maddison et al., 2006). The *T.*  
88 *antarctica* RS and *P. glacialis* RS sub-laminae from both sites, and from both time intervals, occur  
89 at the top of late summer/autumn terrigenous-rich diatom laminae, which supports the contention  
90 that these two diatoms have broadly similar ecological preferences (Stickley et al., 2005).  
91 However, as pointed out by Denis et al. (2006), the more coastal position of the Mertz Ninnis  
92 Trough and MD03-2597 core sites (and associated *P. glacialis* RS sub-laminae) compared to the  
93 core site MD03-2601 (and associated *T. antarctica* RS sub-laminae) suggests that *P. glacialis*  
94 prefers cooler temperatures with higher sea ice concentrations than *T. antarctica*. In this study we  
95 review the available ecological information for these two diatom species. We then consolidate the  
96 perceived relationship between the two taxa as sedimentary indicators of autumnal conditions using  
97 laminated sediment sequences and published ecological information. Finally, we investigate down-  
98 core Holocene diatom assemblage records from two sites in coastal East Antarctica in order to  
99 establish whether the relationship developed from laminated sediment records and ecological  
100 information can be used as a more quantitative proxy for changing environmental conditions during  
101 the Late Quaternary.

102

### 103 1.1. Ecology of *Thalassiosira antarctica* Comber 1896

104

105 *Thalassiosira antarctica* is an Antarctic diatom species rarely found living within sea ice (Hasle and  
106 Heimdal, 1968; Leventer and Dunbar, 1987; Fryxell and Kendrick, 1988; Zielinski and Gersonde,  
107 1997), however, it is commonly described as a sea ice-associated diatom (i.e. living in waters with a  
108 high concentration of sea ice) linked with low sea surface temperature (SST) and low sea surface  
109 salinity (SSS) (Villareal and Fryxell, 1983). Blooms of *T. antarctica* are often recorded in waters  
110 associated with newly forming sea ice, such as the formation of platelet ice next to the Ross Sea ice

111 shelf (Cunningham and Leventer, 1998) and both frazil ice and platelet ice in the Weddell Sea  
112 (Smetacek et al., 1992; Gleitz et al., 1998). In the Weddell Sea, it has also been recorded under  
113 turbulent conditions (Gleitz et al., 1998) and from low salinity, nitrate-deplete, high pH crackpools  
114 associated with summer melting ice (Gleitz et al., 1996). Although it is rare to find *T. antarctica* in  
115 sea ice samples due to its requirement for open water to bloom (Bárcena et al., 1998) and its  
116 sensitivity to low light intensities (Doucette and Fryxell, 1985; Fryxell et al., 1987), it has been  
117 observed in some spring sea ice samples which suggests over-wintering in sea ice or re-suspension  
118 from the sediments (Villareal and Fryxell, 1983).

119  
120 *Thalassiosira antarctica* appears to be a summer and autumn bloom species. It has been observed  
121 as a common component of the early summer phytoplankton around the Antarctic Peninsula  
122 (Sommer, 1991) and was recorded in summer sediment traps in the Ross Sea (Leventer pers. comm.  
123 in Taylor and McMinn, 2002). It has been described as a major component of phytoplankton  
124 blooms in non-stratified or weakly stratified Antarctic surface waters (Cremer et al., 2003) (strong  
125 water column stratification is usually associated with spring sea ice melt). *T. antarctica* has also  
126 been associated with autumn bloom conditions in the Ross Sea with production of resting spores  
127 related to the seasonally-late development of solid ice cover (Cunningham and Leventer, 1998).

128  
129 However, contrary to these observations of natural populations, laboratory culture experiments  
130 revealed that *T. antarctica* can grow well in reduced light conditions in temperatures as low as  $-4^{\circ}\text{C}$   
131 (Bartsch, 1989; Aletsee and Jahnke, 1992), and that vegetative *T. antarctica* cells can survive in sea  
132 ice (Aletsee and Jahnke, 1992) and for prolonged periods of darkness (up to 214 days) without  
133 forming resting spores (Peters and Thomas, 1996a). It is believed that the formation of  
134 physiologically resting cells (identical in appearance to the vegetative cells) is induced by nutrient  
135 stress (Peters and Thomas, 1996b), or by low light intensities beneath the summer diatom bloom  
136 and/or associated nutrient depletion (Taylor and McMinn, 2001). However, culture experiments

137 carried out at  $-1.5^{\circ}\text{C}$  failed to induce resting spore formation by nitrogen depletion (Villareal and  
138 Fryxell, 1983). Significant lipid accumulation occurs in the resting spores as they form (Doucette  
139 and Fryxell, 1985) and this lipid synthesis has been attributed to a synergistic interaction between  
140 reduced light levels, reduced SST and increased SSS in other Antarctic sea-ice related  
141 phytoplankton species (Smith and Morris, 1980; Palmisano and Sullivan, 1982). In conclusion, the  
142 exact trigger for resting spore formation in *T. antarctica* is not well understood.

143  
144 Observations of *T. antarctica* from the sediment record are almost exclusively the resting spore  
145 stage (Fryxell et al., 1981) (Figure 2). *T. antarctica* resting spores are heavily silicified and this has  
146 been suggested as a mechanism to facilitate rapid sinking out of freezing surface waters (Doucette  
147 and Fryxell, 1985). The heavily silicified resting spores are more readily transported, hence, often  
148 become concentrated in Antarctic near-coastal sediments (Gersonde and Wefer, 1987; Hemer and  
149 Harris, 2003). From spatially extensive surface sediment records, *T. antarctica* resting spores are  
150 most abundant beneath regions where February SSTs of  $0$  to  $0.5^{\circ}\text{C}$  and where sea ice is present for  
151 at least 6 months per year with winter sea ice concentrations  $>70\%$  and unconsolidated summer sea  
152 ice concentrations between  $15$ - $40\%$  (Armand et al., 2005). Early Holocene sediments from Prydz  
153 Bay are characterised by abundant *T. antarctica* resting spores (average of  $31\%$  of the assemblage)  
154 and this has been related to seasonally warmer, more open marine conditions (Taylor and McMinn,  
155 2002; Taylor and Leventer, 2003). In the Bransfield Strait, western Antarctic Peninsula, maximum  
156 abundance of *T. antarctica* resting spores in Holocene sediments is related to cold climate episodes  
157 (Bárcena et al., 1998), persistent influence of cold Weddell Sea water (Gersonde and Wefer, 1987;  
158 Leventer, 1991; Zielinski and Gersonde, 1997) and proximity to ice edge (Heroy et al., 2008). In  
159 deglacial and Holocene seasonally laminated Antarctic coastal sediments, *T. antarctica* resting  
160 spores commonly dominate the last recorded flux of the season, indicating their prior prevalence in  
161 mid- to late-summer blooms (as vegetative cells) and a relationship with falling temperatures (ice  
162 formation) and falling light levels (Maddison et al., 2005; Stickley et al., 2005).

163

164 1.2. Ecology of *Porosira glacialis* (Grunow) Jörgensen 1905

165

166 Generally, less is known about the ecological preferences of *Porosira glacialis* than for *T.*167 *antarctica*. *Porosira glacialis* is a bipolar diatom species associated with cold coastal waters

168 adjacent to sea ice (Hasle, 1973; Taylor et al., 1997; Zielinski and Gersonde, 1997). Of the two

169 species of Antarctic *Porosira*, *P. pseudodenticulata* is commonly observed living in pack ice and170 fast ice samples whereas *P. glacialis* is rarely recorded living in sea ice (Watanabe, 1988; Scott et171 al., 1994; Armand, 1997). It has been suggested that *P. glacialis* predominantly grows in the open172 ocean beyond the sea ice edge (Zielinski and Gersonde, 1997), however, *P. glacialis* has been

173 observed in waters with high concentrations of slush and wave-exposed shore ice although, again,

174 not living within the ice (Krebs et al., 1987). Similar to *T. antarctica*, in culture experiments, *P.*175 *pseudodenticulata* survived prolonged periods of darkness (up to 272 days) by forming

176 physiologically resting cells, not by forming resting spores (Peters and Thomas, 1996a). Resting

177 spore formation was not induced at -1.5°C (Villareal and Fryxell, 1983), and the exact mechanism

178 that promotes resting spore formation is not known.

179

180 *P. glacialis* is recorded in sediments predominantly as resting spores (Figure 2) and located181 shoreward of the maximum winter sea ice extent (Armand, 1997). From the sediment record, *P.*182 *glacialis* appears to grow in summer waters with SSTs ranging from -2 to 1.5°C (slightly cooler183 maximum temperature than *T. antarctica*) (Zielinski and Gersonde, 1997), and reaches maximum

184 abundances with February SSTs of 0 to 0.5°C (Armand et al., 2005). From a spatially extensive

185 sediment surface data set, *P. glacialis* is most abundant beneath regions that experience at least 7.5186 months per year sea ice cover (slightly longer than *T. antarctica*), with <30% summer sea ice

187 concentration and highly compacted winter sea ice (65-85% concentration) (Armand et al., 2005).

188 In deglacial, seasonally laminated sediments from Iceberg Alley, Mac.Roberston Shelf, *P. glacialis*

189 RS are abundant in *Thalassiosira antarctica* RS sub-laminae that record the final flux event of the  
190 year, thus suggesting a similarity in their growth requirements (Stickley et al., 2005). In Holocene  
191 laminated sediments from the Mertz-Ninnis Trough, George V Coast, *P. glacialis* RS sub-laminae  
192 are interpreted as representing late summer/autumn deposition as sea ice concentration in the Mertz  
193 Glacier polynya increased (Maddison et al., 2006).

194

195

## 196 2. Materials and Methods

197

### 198 2.1. Materials

199

200 This study uses a suite of Late Quaternary sediment cores recovered from the East Antarctic  
201 margin. Cores from Mertz Ninnis Trough (NBP0101 JPC10/KC10A), Iceberg Alley (NBP0101  
202 JPC43B) and Svenner Channel (NBP0101 JPC24) were recovered during RVIB *Nathaniel B.*  
203 *Palmer* cruise NBP0101 during 2001 (Table 1, Figure 1). Cores from the Dumont d'Urville Trough  
204 (MD03-2597/MD03-2601) were recovered during the MD130-Images X-CADO cruise of RV  
205 *Marion Dufresne II* in 2003 (Table 1, Figure 1). All cores are, in part, seasonally laminated with  
206 the remaining stratigraphy being either intermittently laminated or homogenous siliceous-mud ooze  
207 (Crosta et al., 2005; Leventer et al., 2006; Maddison, 2006; Maddison et al., 2006). Intervals  
208 selected for lamina-scale analyses and down-core diatom assemblage analysis in this study are  
209 illustrated in Figure 1 and listed in Table 1.

210

211 The early Holocene and Neoglacial (Figure 1) laminated sediment sequences from Mertz Ninnis  
212 Trough were deposited approximately 30 km from the coast, beneath the site of a persistent winter  
213 polynya (Maddison et al., 2006). The two cores from Dumont d'Urville Trough were recovered  
214 from biogenic drift deposits that accumulated in small depressions, approximately 30 km and 60 km

215 offshore, within the trough (Crosta et al., 2005). The Dumont d'Urville Trough region is an open  
216 coastline with a typical regime of advance and retreat of seasonal sea ice, with the episodic presence  
217 of a polynya (Arrigo and Van Dijken, 2003). Today, the sites are covered by sea ice for 8-9 months  
218 of the year (Schweitzer, 1995). During the deposition of the deglacial laminated sediments in  
219 Iceberg Alley the long, across-shelf trough that comprises the basin was surrounded by a calving  
220 bay re-entrant (Leventer et al., 2006). This meant that even though the site is approximately 70 km  
221 offshore today, it would have been subject to a seasonal sea ice retreat and advance regime typical  
222 of more coastal sites. Svenner Channel is a coast-parallel trough on the eastern margin of Prydz  
223 Bay. The core site is approximately 60 km from the coast and is subject to a typical seasonal sea  
224 ice advance and retreat regime that results in a yearly sea ice presence of 10 months.

225

226 2.2. *Lamina analyses: BSEI and LM sediment fabric analysis and quantitative diatom*  
227 *assemblage analysis*

228

229 Laminated sediments (Figure 1) were embedded in resin and polished thin sections were produced  
230 for microscope analysis following the methods outlined in Maddison et al. (2006, NBP0101  
231 JPC10/KC10A, MD03-2597), Denis et al. (2006, MD03-2601) and Stickley et al. (2005, NBP0101  
232 JPC43B). Laminated sequences (polished thin sections) were logged for sediment fabric and  
233 diatom assemblages at the 100 micron-scale using either scanning electron microscopy  
234 backscattered electron imagery (BSEI, Pike and Kemp, 1996; Pearce et al., 1998) or optical light  
235 microscopy (LM, Denis et al., 2006) (Table 2). For core sites NBP0101 JPC10/KC10A and MD03-  
236 2597 additional quantitative diatom assemblage analyses were carried on specific lamination types  
237 following the method outlined in Maddison et al. (2006). These additional analyses facilitated  
238 quantitative comparison of the relative abundance of *T. antarctica* RS and *P. glacialis* RS in the  
239 laminations, as opposed to the more qualitative techniques involved in thin section analysis using  
240 BSEI and LM. Data are presented as absolute abundance (valves per gramme), relative abundance

241 and *Hyalochaete Chaetoceros* resting spore-free (CRS-free) relative abundance (Table 3). CRS-  
242 free abundance is commonly used in Antarctic diatom assemblage analysis when CRS  
243 overwhelmingly dominate every assemblage (Leventer et al., 1996; Allen et al., 2005). The CRS-  
244 free abundance allows the ecological information within the minor species assemblage to be  
245 critically examined.

246

### 247 2.3. *Down-core quantitative diatom assemblage analysis*

248

249 Down-core quantitative diatom assemblage analysis was carried out on MD03-2601 (Dumont  
250 d'Urville Trough) and NBP0101 JPC24 (Svenner Channel) following the methods outlined in  
251 Crosta et al. (2007). These records allow the relationship between *T. antarctica* RS and *P. glacialis*  
252 RS, deduced from lamination-scale analyses of mainly deglacial sediments, to be investigated over  
253 the duration of the Holocene. *Porosira glacialis* RS and *P. pseudodenticulata* RS are grouped  
254 together, however, *P. glacialis* RS overwhelmingly dominates the group. *P. pseudodenticulata* has  
255 no distinct central annulus, a slightly larger diameter and fewer areolae in 10  $\mu\text{m}$  (~60-80  $\mu\text{m}$ ; 10-  
256 12) than *P. glacialis* (30-40  $\mu\text{m}$ ; 25-26) which often has a distinct central annulus. The two forms  
257 of *T. antarctica* RS are grouped (T1 and T2, Buffen et al., 2007), however, the cool *T. antarctica*  
258 RS form (T1) overwhelmingly dominates in both Dumont d'Urville Trough and Svenner Channel  
259 sediments.

260

### 261 2.4. *Modelled Holocene surface temperatures and sea ice concentrations*

262

263 The diatom abundance and sediment fabric data and interpretations will be compared with the  
264 results of a 9000-yr Holocene climate simulation using the ECBilt-CLIO-VECODE coupled  
265 atmosphere-sea ice-ocean-vegetation model forced with annually varying orbital parameters  
266 (monthly insolation at 60°S) and atmospheric greenhouse gas (carbon dioxide and methane)

267 concentrations derived from ice cores (Opsteegh et al., 1998; Goosse and Fichefet, 1999; Brovkin et  
268 al., 2002; Renssen et al., 2005). In the model, the vernal equinox is fixed at day 81 and the year is  
269 divided into 12 months of 30 days. All other forcings (e.g. solar constant, other greenhouse gases,  
270 ice sheet configuration) are set at AD 1750 values, hence, changes in ice sheet volume are not taken  
271 into account in the simulation used here. As well as comparing with the published East Antarctic  
272 modelled summer temperature record of Renssen et al. (2005), we will also compare our results to a  
273 sub-set of the whole model output for the Adélie Land sector that encompasses the Dumont  
274 d'Urville Trough core sites (south of 60°S, 140°E-150°E). Two 1000-year time periods from the  
275 Adélie Land mean monthly surface temperature and sea ice concentrations were selected to provide  
276 a measure of typical mean monthly conditions; the interval 4999-4000 yr BP was selected as typical  
277 of the Hypsithermal and 1999-1000 yr BP selected as representative of the Neoglacial. These two  
278 time periods were compared to investigate statistically significant differences in modelled monthly  
279 parameters between the Hypsithermal and Neoglacial. Significant differences in the means were  
280 found using a standard z-test (with 2-tailed critical values) for assessing differences in the means  
281 between large sample sets (Table 4).

282

### 283 **3. Results**

284

#### 285 *3.1 Laminated sediments – BSEI, LM and quantitative diatom assemblage analysis*

286

287 Data for the lamina-scale diatom assemblage analyses, using BSEI, LM and quantitative abundance,  
288 come from both published sources and from new analyses. BSEI lamina characterisations for  
289 sediments from the Mertz-Ninnis Trough (NBP0101 JPC10/KC10A) are summarised from  
290 Maddison (2006) and Maddison et al. (2006). Similar data for the Dumont d'Urville Trough  
291 (MD03-2597) are summarised from Maddison (2006) and LM lamina data (MD03-2601) are  
292 summarised from Denis et al. (2006). Lamina-scale diatom assemblage data for sediments from

293 Iceberg Alley (NBP0101 JPC43B) are a combination of both published (Stickley et al., 2005,  
294 interval 21.84-23.96 m) and previously unpublished data (Stickley and Pike: interval 19.30-21.84  
295 m). Tables 2 and 3 provide a summary of these data containing only the lamina or sub-lamina data  
296 relevant to this study.

297

### 298 3.1.1. *Thalassiosira antarctica* RS sub-laminae

299 Analysis of lamina occurrence data from the spectacularly laminated deglacial sediments of the East  
300 Antarctic margin reveals that when sub-laminae characterised by *T. antarctica* RS or *P. glacialis*  
301 RS occur, usually: (1) either one or the other species is dominant; and (2) they are found in a similar  
302 position within the seasonal succession of diatom assemblages and lamina types, i.e. at the end of  
303 the season of diatom production and subsequent flux to the sediment, late summer or autumn  
304 (Stickley et al., 2005; Denis et al., 2006; Maddison, 2006). In deglacial Iceberg Alley sediment, 43  
305 of 68 *T. antarctica* RS sub-laminae occur in this position above a summer lamina (Table 2) and,  
306 consequently, directly below the following spring diatom ooze lamina from which they are  
307 separated by a sharp contact delineating the winter hiatus. Further, when a summer lamination is  
308 not present, 25 of 68 occurrences of *T. antarctica* RS sub-laminae follow a transitional lamination  
309 (Table 2), defined as having some characteristics of both spring diatom ooze laminae and summer  
310 terrigenous-rich laminae (Stickley et al., 2005). These transitional laminae nearly always grade  
311 upwards from a spring diatom ooze lamina and usually grade into a summer terrigenous-rich  
312 lamina, however, sometimes these transitional laminae are abruptly overlain by the following spring  
313 diatom ooze laminae. Usually, it is at the top of these latter transitional laminae that *T. antarctica*  
314 RS sub-laminae occur. When *T. antarctica* RS sub-laminae occur within the annual sediment  
315 increment, the mean annual sediment thickness is 2% greater than if sub-laminae do not occur.  
316 Further, if a summer lamination is followed by a *T. antarctica* RS sub-lamina, the summer lamina  
317 is, on average, 7% thicker than one that is not associated with a sub-lamina (Table 2). Qualitative

318 analysis of *T. antarctica* RS sub-laminae from Iceberg Alley also reveals that *P. glacialis* RS are  
319 more abundant in the sub-laminae than in the summer, terrigenous-rich laminae.

320

321 LM analysis of lamina sequences from the Holocene sediments of the less coastal MD03-2601 core  
322 from Dumont d'Urville Trough shows the presence of sub-laminae of *T. antarctica* RS associated  
323 with late summer/autumn in Hypsithermal-age sediments and the absence of the sub-laminae in  
324 Neoglacial-age sediments (Table 2, Denis et al., 2006). During the Hypsithermal period, annual  
325 sediment thickness was 46 mm compared with 21 mm during the Neoglacial, and mean thickness of  
326 *T. antarctica* RS sub-laminae during the Hypsithermal was 0.371 mm (Table 2, Denis et al., 2006).  
327 In contrast to the other, more coastal core site from Dumont d'Urville Trough (MD03-2597) these  
328 sections from MD03-2601 do not contain any *P. glacialis* RS sub-laminae during the Neoglacial.

329

### 330 3.1.2 *Porosira glacialis* RS sub-laminae

331 Nineteen out of twenty two occurrences of *P. glacialis* RS sub-laminae in deglacial Mertz-Ninnis  
332 Trough sediment appear in a late summer/autumn position in the seasonal lamina succession (Table  
333 2). Quantitative diatom abundance analysis of Mertz-Ninnis Trough laminations reveals that  
334 although, in absolute terms, *P. glacialis* RS have a similar abundance in summer mixed diatom  
335 laminae as they do in *P. glacialis* RS sub-laminae (Table 3, Maddison et al., 2006), *P. glacialis* RS  
336 comprise, on average, 11.35% of the CRS-free assemblage in *P. glacialis* RS sub-laminae and only  
337 2.29% in the summer mixed assemblage laminae (Table 3, Maddison et al., 2006). At this site, *T.*  
338 *antarctica* RS are absent from both the summer mixed diatom laminae and the *P. glacialis* RS sub-  
339 laminae (Table 3, Maddison et al., 2006). When a *P. glacialis* sub-lamina occurs within the annual  
340 sediment increment, the mean annual sediment thickness is 18% greater than if a sub-lamina does  
341 not occur (Table 2). BSEI analysis of a 0.28 m-long (17 year) sequence of early Neoglacial-age  
342 laminations from this site (NBP0101 KC10A; Table 1 and Figure 1) does not reveal any *T.*  
343 *antarctica* RS or *P. glacialis* RS sub-laminae (Maddison, 2006).

344

345 In Neoglacial laminated sediments from the more coastal Dumont d'Urville Trough core (MD03-  
346 2597), in 23 out of 26 years when *P. glacialis* RS sub-laminae occur, the sub-laminae appear in a  
347 late summer/autumn position (Table 2, Maddison, 2006), separated with a sharp contact from the  
348 overlying spring lamination. Quantitative diatom abundance analysis reveals that, in absolute  
349 terms, *P. glacialis* RS are more than 2.5 times as abundant in *P. glacialis* RS sub-laminae than they  
350 are in terrigenous-rich, summer mixed assemblage laminae. Further, *T. antarctica* RS are more  
351 than 2.5 times as abundant in *P. glacialis* RS sub-laminae than in terrigenous-rich, summer mixed  
352 assemblage laminae (Table 3, Maddison, 2006). When *P. glacialis* RS sub-laminae occur within  
353 the annual sediment increment, the mean annual sediment thickness is 12% greater than if sub-  
354 laminae do not occur (Table 2).

355

### 356 3.2. Holocene records from Dumont d'Urville Trough and Svenner Channel

357

358 Holocene relative abundance of *T. antarctica* RS and *P. glacialis* RS from Dumont d'Urville  
359 Trough (MD03-2601) and Svenner Channel (NBP0101 JPC24) (Figure 1) are shown in Figure 3. In  
360 general, at both sites, relative abundances of *T. antarctica* RS are higher than *P. glacialis* RS. In  
361 the Dumont d'Urville Trough, the relative abundance of *T. antarctica* RS steadily rises to a peak at  
362 ~8.9 cal kyr BP (Figure 3B). Abundance then generally stays above 10% until ~3.4 cal kyr BP  
363 when it falls below 10% until ~2 cal kyr BP. Abundance then becomes very low (<5%) between 2  
364 cal kyr BP until ~1.1 cal kyr BP, after which it recovers to about 10% at the top of the core.  
365 Relative abundance of *P. glacialis* RS displays an approximately inverse pattern. Abundance  
366 remains above 2% from ~10.8 cal kyr BP until ~8.7 cal kyr BP (Figure 3C), with a slight dip in  
367 abundance around 9.8 cal kyr BP. At 8.7 cal kyr BP, abundance falls abruptly below 2% until ~3.4  
368 cal kyr BP, when it abruptly rises to above 2% until ~2.8 cal kyr BP when it falls below, and stays

369 below, 2% until ~2 cal kyr BP. After 2.0 cal kyr BP, abundance rises to above 2% and then steadily  
370 falls towards the top of the core (~1 cal kyr BP).

371

372 In Svenner Channel, *T. antarctica* RS relative abundance rises from 11.2 cal kyr BP to a peak of  
373 >20% around 9.8 cal kyr BP (Figure 3E). Abundance dips below 20% around 9 cal kyr BP, rises to  
374 above 20% at ~8.7 cal kyr BP and then increases steadily to a peak at ~4.4 cal kyr BP. Relative  
375 abundance begins to decline and falls below 20% at ~3.4 cal kyr BP; it remains below 20% until the  
376 top of the core (~0.67 cal kyr BP). The relative abundance of *P. glacialis* RS remains below ~2%  
377 from 11.2 cal kyr BP until ~8.7 cal kyr BP when it begins to steadily rise (Figure 3F). At ~4.3 cal  
378 kyr BP, abundance rises above 2% and stays high until ~1 cal kyr BP when it falls below 2 % at the  
379 top of the core.

380

381 The relationship between *T. antarctica* RS and *P. glacialis* RS can be further investigated by  
382 looking at the ratio between the two diatoms, and also the statistical correlation between the two  
383 species curves. The ratio between *P. glacialis* RS and *T. antarctica* RS (i.e. relative abundance of  
384 *P. glacialis* RS/relative abundance of *T. antarctica* RS) in Dumont d'Urville Trough is approaching  
385 0.5 from the base of the core (~10.8 cal kyr BP) until ~10 cal kyr BP where it abruptly falls to very  
386 low values (Figure 3D). The ratio remains very low until ~3.4 cal kyr BP when it abruptly rises to  
387 >0.1 up to the top of the core (~1 cal kyr BP). Between ~2.8 cal kyr BP and ~2 cal kyr BP, the ratio  
388 falls, however, generally remains above 0.1. In Svenner Channel, the ratio between *P. glacialis* RS  
389 and *T. antarctica* RS remains generally <0.1 from ~11.2 cal kyr BP until ~4.3 cal kyr BP when it  
390 begins to rise (Figure 3G). The ratio reaches peak values (~0.5) at ~2.8 cal kyr BP and generally  
391 remains above 0.2 up to the top of the core (~0.7 cal kyr BP). The Pearson correlation coefficient  
392 ( $r$ ) between the relative abundance of *T. antarctica* RS and *P. glacialis* RS is -0.19 for the Dumont  
393 d'Urville record (n=528). This correlation coefficient appears weak, but a test of significance of  $r$   
394 demonstrates that threshold for significant values of  $r$  for sample sizes of n=528, at the 99%

395 significance level, is 0.14 (Lowry, 2008). There is no significant correlation between the relative  
396 abundances of *T. antarctica* RS and *P. glacialis* RS in the Svenner Channel record. The correlation  
397 coefficient is negative, but not significant ( $r=-0.0004$ ;  $n=348$ ). However, the significant negative  
398 correlation between *T. antarctica* RS and *P. glacialis* RS for Dumont d'Urville Trough supports the  
399 qualitative observations of an inverse relationship between the two taxa.

400

401 The diatom relative abundance curves are also compared with the modelled mean October to April  
402 (i.e. austral summer) surface temperature record for the Holocene of East Antarctica (Renssen et al.,  
403 2005) (Figure 3A). The modelled surface temperature record reveals temperatures warming from  
404  $\sim 0.4^{\circ}\text{C}$  warmer than pre-industrial levels at 9.0 kyr BP, to temperatures  $\sim 1.0^{\circ}\text{C}$  warmer than pre-  
405 industrial levels at  $\sim 4.3$  kyr BP. Modelled temperatures then decline steadily until the end of the  
406 record, approximately 300 yr BP. The Pearson correlation between the relative abundance of *T.*  
407 *antarctica* RS and modelled mean summer temperature in Dumont d'Urville Trough and Svenner  
408 Channel is 0.44 and 0.64, respectively. The Pearson correlation between the relative abundance of  
409 *P. glacialis* RS and modelled mean summer temperature in Dumont d'Urville Trough and Svenner  
410 Channel is -0.48 and -0.11, respectively. The Pearson correlation between the modelled mean  
411 summer temperature and the ratio *P. glacialis* RS:*T. antarctica* RS is -0.55 for Dumont d'Urville  
412 Trough and -0.40 for Svenner Channel. All but one of these correlation coefficient values are above  
413 the threshold values of the Pearson's test of significance ( $r=-0.11$  falls below the threshold). This  
414 highlights a positive correlation between the relative abundance of *T. antarctica* RS and modelled  
415 mean summer temperature; a negative correlation between relative abundance of *P. glacialis* RS  
416 and modelled mean summer temperature; and a more robust negative correlation between the ratio  
417 *P. glacialis* RS:*T. antarctica* RS and modelled mean summer temperature.

418

#### 419 **4. Interpretation and Discussion**

420

421 4.1. Mechanism for formation of *T. antarctica* and *P. glacialis* resting spore sub-laminae

422

423 When sub-laminae characterised by *T. antarctica* RS or *P. glacialis* RS occur in the laminated  
424 sediments from the East Antarctic margin, three features are consistent: (1) one or the other species  
425 is dominant; (2) the sub-laminae predominantly occur in the same position within the seasonal  
426 sedimentary sequence – late summer to autumn; and (3) overall annual sediment thickness is greater  
427 when sub-laminae are present (in deglacial Iceberg Alley sediments, the sub-laminae are also  
428 associated with summer laminations that are thicker than average indicating increased summer  
429 production and flux to the sediments). Hence (2) and (3) can be interpreted together as indicating  
430 that the sub-laminae are associated with years of higher diatom flux to the sediment. The  
431 occurrence of *T. antarctica* RS and *P. glacialis* RS sub-laminae (and thicker summer laminations)  
432 could indicate either a longer duration summer season of diatom productivity, promoting greater  
433 overall flux to the sediment, or enhanced summer conditions that favour higher *T. antarctica* and *P.*  
434 *glacialis* vegetative production, hence production and flux of the resting spores to the sediment in  
435 autumn.

436

437 *Thalassiosira antarctica* RS and *P. glacialis* RS sub-lamina production is likely to be related to a  
438 slow break up of sea ice over a sustained period in spring, i.e. a slow increase of temperatures over  
439 a few weeks so that when light levels increase sufficiently to promote vegetative cell growth there is  
440 a relatively high sea ice concentration that significantly effects surface water properties. *Porosira*  
441 *glacialis* and *T. antarctica* have both been found associated with spring sea ice-rich regions  
442 (Villareal and Fryxell, 1983; Krebs et al., 1987). Relatively high spring sea ice concentrations  
443 would lead to summer production favouring sea ice-associated diatoms such as *T. antarctica* and *P.*  
444 *glacialis* (standing stocks enhanced by ‘icy’ spring) and both species are known to be abundant in  
445 Antarctic summer waters (Sommer, 1991; Zielinski and Gersonde, 1997; Cremer et al., 2003).  
446 Finally, sea ice formation in the autumn, accompanied by lowering SSTs, increased salinity and

447 lowering light levels (Doucette and Fryxell, 1985; Fryxell et al., 1987; Cunningham and Leventer,  
448 1998), would induce resting spore formation from a vegetative population that was sufficiently  
449 large to produce a sub-lamina in the sediments (Stickley et al., 2005; Denis et al., 2006; Maddison  
450 et al., 2006). Years without sub-laminae suggest more rapid melting and break-up of sea ice in  
451 spring favouring more marginal ice zone/open water species and reduced growth of *T. antarctica*  
452 and *P. glacialis* in the subsequent summer. Lower summer vegetative populations of *T. antarctica*  
453 and *P. glacialis* would not lead to the production of sufficient numbers of resting spores to produce  
454 a sub-lamina in autumn.

455  
456 Key to confirming this sea ice-based model of sub-lamina formation are the two cores from Dumont  
457 d'Urville Trough which are geographically close to each other and would have experienced similar  
458 changes in external forcing (i.e. by insolation and greenhouse gases). At MD03-2601, during the  
459 Hypsithermal, *T. antarctica* RS sub-laminae were preserved (core MD03-2597 did not recover  
460 Hypsithermal-age sediments). In the Neoglacial, no sub-laminae of either species were preserved at  
461 site MD03-2601, although higher relative abundances of *P. glacialis* RS are observed (Figure 3C),  
462 whereas *P. glacialis* RS sub-laminae were preserved at MD03-2597 (Table 2). In the modern day,  
463 site MD03-2597 is covered by less than 65% sea ice concentration for, on average, 111 days of the  
464 year, whereas site MD03-2601 is subject to less than 65% sea ice concentration for only 94 days of  
465 the year (difference between means is significant at >95%; mean values extracted from satellite-  
466 derived daily sea ice concentrations for 26 years between 1979 and 2006, National Snow and Ice  
467 Data Centre, <http://nsidc.org/data/nsidc-0079.html>). Site MD03-2597 becomes 'ice-free'  
468 (consistently less than 65% sea ice concentration), on average, 19 days earlier in the spring than site  
469 MD03-2061 because the ice-edge not only retreats parallel with the coastline, but also retreats in a  
470 westward direction along the coast towards the Dumont d'Urville Trough. This is due to the areal  
471 expansion of the coastal Mertz Glacier Polynya, which merges with the open ocean in summer. So,  
472 not only are there less ice-free days at MD03-2601, the sea ice retreats later in the spring. The

473 combined evidence of higher relative abundance of *P. glacialis* RS (MD03-2601) and the presence  
474 of *P. glacialis* RS sub-laminae (MD03-2597) in Neoglacial sediments, along with the cessation of *T.*  
475 *antarctica* RS sub-laminae formation (MD03-2601), suggests that increasingly higher winter and  
476 spring sea ice concentrations occurred in the Dumont d'Urville Trough region in the Neoglacial,  
477 relative to the Hypsithermal period. Perhaps the environment became either too icy (given modern  
478 seasonal sea ice differences detailed above) or, more likely, had too short an ice-free summer  
479 season at site MD03-2601 during the Neoglacial for even *P. glacialis* to be able to form large  
480 enough populations to promote significant flux of resting spores to the sea floor and subsequent  
481 sub-laminae formation.

482

#### 483 4.2. *Environmental controls on the P. glacialis RS:T. antarctica RS ratio in Holocene sediments*

484

485 From the lamination data, *T. antarctica* RS and *P. glacialis* RS sub-laminae are both interpreted as  
486 representing years with relatively high spring sea ice concentrations, however, what threshold under  
487 these conditions would govern changes in the relative abundance of the two species seen throughout  
488 the Holocene (Figure 3), given that they appear to have similar ecologies? Here we combine our  
489 sea ice-based mechanism of sub-lamina formation with published ecological preferences and  
490 modelled Holocene surface temperature and sea ice concentrations from the Adélie Land sector  
491 (Table 4, Figure 4) to present a model of the environmental conditions that alter the relative  
492 abundance of *T. antarctica* RS and *P. glacialis* RS in the sediments.

493

494 *P. glacialis* appears to prefer somewhat higher winter and spring sea ice concentrations than *T.*  
495 *antarctica*. Maximum abundances of *P. glacialis* RS in the sediment are found beneath regions  
496 subject to >7.5 months per year sea ice cover (*T. antarctica* prefers >6 months), <30% summer sea  
497 ice concentration (*T. antarctica* similar) and highly compacted winter sea ice (up to 85%  
498 concentration; *T. antarctica* prefers slightly less, but still >70%) (Armand et al., 2005). These

499 ecological observations are supported by our Holocene records and comparisons with the modelled  
500 summer surface temperatures from East Antarctica (Renssen et al., 2005). Increased abundance of  
501 *T. antarctica* RS in the sediments from Dumont d'Urville Trough and Svenner Channel is positively  
502 correlated with modelled summer surface temperatures whereas increased abundance of *P. glacialis*  
503 RS is negatively correlated with modelled summer surface temperatures (Figure 3).

504

505 The modelled sea ice concentration and surface temperature records for the Adélie Land sector  
506 suggest that the cool Neoglacial period had higher winter and early spring sea ice concentrations  
507 than the mid Holocene Hypsithermal (Table 4, Figure 4), with significantly lower late spring and  
508 early summer temperatures. In autumn, the Neoglacial had lower sea ice concentrations than the  
509 Hypsithermal with slightly higher temperatures. This model output supports the interpretation from  
510 ecological and seasonal sedimentological data that *P. glacialis* prefers slightly cooler and 'icier'  
511 winter and spring conditions than *T. antarctica*, which is why its abundance was enhanced during  
512 the Neoglacial off both Adélie Land and Princess Elizabeth Land. A subsequent long  
513 summer/autumn season, as suggested by the model data, would favour the build-up of larger  
514 populations of *P. glacialis* and concomitantly reduced populations of *T. antarctica*. Our  
515 interpretations are in agreement with those of Crosta et al. (2008) who state that seasonal sea ice  
516 distribution during the Holocene of East Antarctica is more complicated than a simple pattern of  
517 less sea ice during the warmer Hypsithermal, and more during the cooler Neoglacial.

518

519 4.3. *P. glacialis* RS:*T. antarctica* RS – a new sediment proxy for winter and spring sea ice  
520 concentrations

521

522 The results from Dumont d'Urville Trough (MD03-2601) and Svenner Channel sediments  
523 presented here indicate that 0.1 appears to be a significant threshold value for the ratio *P. glacialis*  
524 RS:*T. antarctica* RS. An increase above 0.1 accompanies an important environmental change to

525 increased winter sea ice concentration, cooler spring seasons with increased sea ice, and slightly  
526 warmer autumn seasons with less sea ice. In the Holocene sediments of coastal East Antarctica, the  
527 ratio changes from  $<0.1$  to  $>0.1$  between 4.3-3.4 cal kyr BP (i.e the transition from warmer  
528 Hypsithermal conditions to cooler, Neoglacial conditions, Masson et al., 2000; Crosta et al., 2007).  
529 However, it is possible to use the ecological information in an attempt to be more quantitative than  
530 this. Using the ecological preferences of *P. glacialis* and *T. antarctica* and its distribution in  
531 modern core top samples (Armand et al., 2005), an increase in the sediment ratio above 0.1 (i.e.  
532 enhanced *P. glacialis* RS and/or relatively reduced *T. antarctica* RS abundance) appears to indicate  
533 a change from  $\sim 7.5$  months of annual sea ice cover (favouring *T. antarctica* production), to much  
534 greater than 7.5 months of annual sea ice cover (enhancing *P. glacialis* production), and an increase  
535 from  $\sim 70\%$  winter sea ice concentration (favouring subsequent *T. antarctica* production) to highly  
536 compacted winter sea ice above 80% concentration (enhancing *P. glacialis* production). Although  
537 these may not seem like large changes, they appear to be key manifestations of the changes between  
538 warmer and cooler Holocene climate states as reflected in the diatom fossil record, and are in line  
539 with the changes suggested by previous diatom evidence for the Hypsithermal-Neoglacial transition  
540 (Crosta et al., 2008).

541  
542 Attempts to apply the *P. glacialis* RS:*T. antarctica* RS proxy to west Antarctic Peninsula (WAP)  
543 diatom records from Palmer Deep (Taylor and Sjunneskog, 2002) and Bransfield Strait (Heroy et  
544 al., 2008) have met with limited success because the relative warmth of the WAP compared to the  
545 East Antarctica margin limits the abundance of *P. glacialis* RS in the sediments to be almost always  
546 less than 10% of *T. antarctica* RS. However, a preliminary analysis of Holocene diatom abundance  
547 records from the cooler NW Weddell Sea has proved promising in that stratigraphic intervals when  
548 *P. glacialis* RS:*T. antarctica* RS was  $>0.1$  (interpreted as representing cool, sea ice-rich winter and  
549 spring conditions) are also intervals of high abundance of other sea ice-related diatoms such as  
550 *Fragilariopsis curta*, *F. cylindrus* and *Thalassiosira tumida* (Anna Hey, personal communication,

551 2008). This demonstrates the potential wider applicability of the *P. glacialis* RS:*T. antarctica* RS  
552 ratio around the Antarctic coast.

553

## 554 5. Conclusions

555

556 This synthesis of information on the abundance of *Thalassiosira antarctica* and *Porosira glacialis*  
557 has shown that these two diatoms have similar ecological preferences. The combination of modern  
558 phytoplankton analyses, laboratory experiments and late Quaternary laminated sediment records  
559 reveals that high fluxes of *T. antarctica* RS and *P. glacialis* RS to the sediment are associated with  
560 prior high winter and spring sea ice concentrations that promote the build-up of large vegetative cell  
561 populations. In late autumn, abrupt sea ice advance, accompanied by decreasing temperatures and  
562 irradiance and increased salinities promotes resting spore formation from high summer/autumn  
563 standing stocks. The investigation of two core records from the Dumont d'Urville Trough and one  
564 from Svenner Channel showed that despite their similar ecological preferences, there were  
565 interesting differences in the Holocene occurrence of the two taxa. Relative abundance of *T.*  
566 *antarctica* RS peaked during the warm mid-Holocene Hypsithermal period and declined into the  
567 cooler Neoglacial, whereas relative abundance of *P. glacialis* RS peaked during the late Holocene,  
568 cool Neoglacial period. Increased *P. glacialis* RS abundance appeared to be linked with higher  
569 winter and spring sea ice concentrations than *T. antarctica* RS. These conclusions are corroborated  
570 by a comparison with modelled Holocene sea ice concentrations and surface temperatures for the  
571 Adélie Land sector. The model output reveals higher winter and early spring sea ice concentrations,  
572 and lower spring and early summer temperatures during the Neoglacial relative to the Hypsithermal  
573 (which would promote increased populations of *P. glacialis*). Investigation of the ratio of relative  
574 abundance of the two diatoms, *P. glacialis* RS:*T. antarctica* RS, revealed that a threshold of 0.1 was  
575 important. The ratio abruptly increased from <0.1 to >0.1 at the Hypsithermal to Neoglacial  
576 transition. An increase in the ratio *P. glacialis* RS:*T. antarctica* RS to greater than 0.1 appears to

577 indicate a change from ~7.5 months of annual sea ice cover to much greater than 7.5 months of  
578 cover, and an increase of winter sea ice concentrations from 70% to >80%. An attempt to apply the  
579 *P. glacialis* RS:*T. antarctica* RS ratio to other core sites from West Antarctica, in particular the NW  
580 Weddell Sea, shows that the relationship between these two diatom species may be able to reveal  
581 information about past winter and spring sea ice concentrations around the Antarctic margin.

589 developed during JP's stay at EPOC, funded by the Invited Professor Scheme of Bordeaux I  
590 University. The climate modelling work was supported by the Netherlands Organization for  
591 Scientific Research (HR). JP would like to thank Captain Joe Borkowski, the Edison Chouest  
592 Offshore crew, the Raytheon Polar Services Company staff and scientific party aboard the RVIB  
593 *Nathaniel B. Palmer* during cruise NBP01-01, and the staff at the Antarctic Research Facility  
594 (Florida State University) for assistance with sampling. We (JP, CES, EJM, XC) particularly  
595 acknowledge discussion and encouragement over many stages of this research by Amy Leventer.  
596 XC personally thanks members of the Images X (CADO) cruise and from cruise NBP01-01 for  
597 providing data and suggestions. Logistical support for Images X (CADO) cruise was provided by  
598 IPEV-TAAF. JP would also like to thank Charlotte Sjunneskog for sharing west Antarctic  
599 Peninsula diatom data sets, and Ian Thomas for assistance in handling the NSIDC satellite daily sea  
600 ice concentration data set. Finally we would like to thank María Ángeles Bárcena Pernía and one  
601 anonymous reviewer for their careful consideration of our manuscript.

762 **Table and Figure Captions**

763

764 Table 1: East Antarctica margin sediment core information, including details of location, length,  
765 distance from coast, core intervals analysed and age of intervals analysed.

766

767 Table 2: Summary of lamina and sub-lamina thickness measurements from BSEI and LM of East  
768 Antarctic laminated sediment sequences.

769

770 Table 3: Quantitative abundance of *Porosira glacialis* RS and *Thalassiosira antarctica* RS from  
771 selected East Antarctic sediment laminae and sub-laminae.

772

773 Table 4: Summary of Adélie Land sector modelled Holocene surface temperature and sea ice  
774 concentrations for typical Hypsithermal (4000-4999 yr BP) and typical Neoglacial (1000-1999 yr  
775 BP) periods (extracted from Renssen et al., 2005). Surface temperatures and sea ice concentrations  
776 are given as anomalies from the pre-industrial mean (1000-250 yr BP).

777

778 Figure 1: Locations of the East Antarctic margin sediment cores used in this investigation. AL =  
779 Adélie Land and PEL = Princess Elizabeth Land. The intervals sampled from each of the cores are  
780 shown by the black (BSEI and LM sediment fabric analyses) and grey (Holocene down-core  
781 quantitative diatom abundance analyses). The presence of *Thalassiosira antarctica* RS sub-laminae  
782 is indicated by white and *Porosira glacialis* RS sub-laminae by a vertical line.

783

784 Figure 2: Light microscope (LM) and scanning electron microscope (SEM) images of  
785 *Thalassiosira antarctica* and *Porosira glacialis* resting spores. SEM micrographs taken of Au-Pd  
786 coated, lamina parallel sediment fracture surfaces. **A-B.** LM micrographs of *T. antarctica* resting  
787 spores (NBP01-01 JPC10, 19.536 cm). **C-D.** Secondary electron SEM micrographs of *T.*

788 *antarctica* resting spores (MD03-2597, 5307.5 cm, scale bars G = 5 microns, H = 10 microns). **E-**  
789 **F.** LM micrographs of *P. glacialis* resting spores (NBP01-01 JPC10, 19.536 cm). **G-H.** Secondary  
790 electron SEM micrographs of *P. glacialis* resting spores (NBP01-01 JPC10, 19.463 cm; scale bars  
791 C = 10 microns, D = 50 microns).

792  
793 Figure 3: Holocene *Thalassiosira antarctica* and *Porosira glacialis* resting spore abundance from  
794 Dumont d'Urville Trough (MD03-2601) and Svenner Channel (NBP01-01 JPC24). **A.** Modelled  
795 mean summer (October to April) surface temperature (relative to the pre-industrial mean (1000-250  
796 yr BP)) from Renssen et al. (2005). **B-D.** Dumont d'Urville Trough records. **B.** Relative  
797 abundance of *T. antarctica* RS. **C.** Relative abundance of *P. glacialis* RS. **D.** Ratio of *P. glacialis*  
798 RS:*T. antarctica* RS. **E-G.** Svenner Channel records. **E.** Relative abundance of *T. antarctica* RS.  
799 **F.** Relative abundance of *P. glacialis* RS. **G.** Ratio of *P. glacialis* RS:*T. antarctica* RS.  
800 Neoglacial and Hypsithermal intervals are defined following Crosta et al. (2005).

801  
802 Figure 4: Schematic diagram illustrating differences modelled sea ice concentrations and surface  
803 temperatures between Hypsithermal and Neoglacial. Differences significant at the 99% confidence  
804 interval are shown with horizontal lines and differences at the 95% confidence interval are shown  
805 with horizontal curves. Where the Hypsithermal and Neoglacial lines overlap there is no  
806 statistically significant difference between the two records.

807

		Transitional lamina thickness	9.52 (9.28)	110	0.73	49.76
		Transitional lamina thickness if followed by <i>T. antarctica</i> RS sub-lamina	8.29 (4.49)	25	1.26	18.42
<i>T. antarctica</i> RS sub-lamina thickness if associated with top of transitional lamina <sup>4</sup>	0.88 (0.81)	25	0.25	3.28		

<sup>1</sup> 26 years have *P. glacialis* RS sub-laminae; 5 years have multiple sub-laminae

<sup>2</sup> 67 years have *T. antarctica* RS sub-laminae; 1 year has 2 sub-laminae

<sup>3</sup> 46 years have *T. antarctica* RS sub-laminae; in 43/46 years the sub-lamina is at the top of the summer lamina; in 3/46 years, the sub-lamina is within the summer laminae

<sup>4</sup> Four transitional laminae, overlain by *T. antarctica* RS sub-laminae, are followed by summer laminae associated with *T. antarctica* RS sub-laminae

Table 3

Location	Sub-lamina type	<i>P. glacialis</i> RS or <i>T. antarctica</i> RS abundance in lamina or sub-lamina types	Mean Abundance (standard deviation) / x 10 <sup>6</sup> valves/g	No. of Measurements (n)	Minimum / x 10 <sup>6</sup> valves/g	Maximum / x 10 <sup>6</sup> valves/g	Relative Abundance (%) All/CRS-free
Mertz-Ninnis Trough (NBP0101 JPC10)	<i>P. glacialis</i> RS	<i>P. glacialis</i> RS abundance in summer mixed diatom lamina	6.9 (2.7)	5	3.9	9.5	0.38 / 2.29
		<i>T. antarctica</i> RS abundance in summer mixed diatom lamina	0 (0)	5	0	0	0 / 0.42
		<i>P. glacialis</i> RS abundance in <i>P. glacialis</i> RS sub-lamina	7.2 (3.9)	4	3.2	10.6	0.24 / 11.35
		<i>T. antarctica</i> RS abundance in <i>P. glacialis</i> RS sub-lamina	0 (0)	4	0	0	0 / 0
Dumont d'Urville Trough (MD03-2597)	<i>P. glacialis</i> RS	<i>P. glacialis</i> RS abundance in summer mixed diatom lamina	20.3 (9.9)	5	10.9	34.8	2.91 / 5.1
		<i>T. antarctica</i> RS abundance in summer mixed diatom lamina	2.4 (3.6)	5	0	8.6	0.39 / 0.81
		<i>P. glacialis</i> RS abundance in <i>P. glacialis</i> RS sub-lamina	53.9 (27.2)	3	33.5	84.8	7.08 / 15.48
		<i>T. antarctica</i> RS abundance in <i>P. glacialis</i> RS sub-lamina	6.7 (6.7)	3	0	13.4	0.89 / 3.16
