### Abstract :

Biogenic reefs composed of the tube-building polychaete *Lanice conchilega* are important from a conservation point of view because they noticeably increase the biodiversity in otherwise species poor environments. However, up to now, little or no attention has been paid to the intertidal epi- and hyperbenthic communities associated with the reefs. Therefore, this is the first study which focuses on the effect of *L. conchilega* reefs on the entire benthic-pelagic community at two different locations. Environmental variables were measured and macro-, epi- and hyperbenthic communities were sampled within a *L. conchilega* reef and a control area at two locations in France: the bay of the Mont Saint-Michel (BMSM) and Boulogne-sur-Mer (Boulogne). The effect of the reef presence on the benthic community was studied with a 3-factor (Reef, Location and Period) Permanova. In addition, the relationship between the benthic community and the environmental variables were investigated using Distance-based linear models (DistLM). Most collected organisms were sampled in the reef area

(macrobenthos: 91 %, epibenthos: 81 % and hyperbenthos: 78.5%) indicating that, independent of the location, the *L. conchilega* reefs positively affect all three associated benthic communities. However, the extent of the effect seems to be most pronounced for the macrobenthos and less distinct in case of the hyperbenthos. The macro-, and epibenthos are mainly structured by biotic variables (*L. conchilega* density and macrobenthic food availability respectively), while the hyperbenthos is rather structured by environmental variables. In general, *L. conchilega* reefs do not only affect abundances and diversity but they substantially steer the structure of the intertidal benthic sandy beach ecosystem.

## 1. Introduction

Numerous organisms are widely known to modify their environments and influence other species. Recently, there has been a growing interest in biota that directly or indirectly modulate the availability of resources (other than themselves) to other species, by causing physical state changes in biotic or abiotic materials, so-called ecosystem engineers (Jones et al., 1994). Typically, ecosystem engineers are classified as either *autogenic* (changing the environment via their own physical structures; e.g. corals) or *allogenic* (changing the environment by transforming living or non-living materials from one physical state to another; e.g. woodpeckers, beavers) ( Jones et al., 1994). In the marine environment, ecosystem engineers are known to strongly modify coastal sediments in temperate, tropical and semi-tropical locations ( Kirtley and Tanner, 1968, Micheletti-Flores and Negreiros-Fransozo, 1999 and Bouma et al., 2009a) and possibly create persistent emergent structures referred to as 'biogenic reefs' ( Carey, 1987, Rabaut et al., 2009, Callaway et al., 2010 and Godet et al., 2011). Seagrass fields (e.g. Bouma et al., 2009b), bivalve accumulations (e.g. Gutiérrez et al., 2003) and polychaete tube assemblages (e.g. Dubois et al., 2002 and Chapman et al., 2012) are some of the most striking biogenic structures composed of ecosystem engineers in coastal environments. A prime example is the aggregations composed of the Sandmason *Lanice conchilega* (Polychaeta, Terebellidae). This species may achieve densities of several thousands of individuals  $m^{-2}$  ( Van Hoey et al., 2006) and as such generate elevated sediment reefs ( Rabaut et al., 2009). *L. conchilega* displays both autogenic (e.g. by

providing oxygen supply) and allogenic (by sedimentological and biological alterations) ecosystem engineering properties (Godet *et al.* 2008; Rabaut *et al.* 2009) and is therefore bound to receive a higher ecosystem engineer qualification (Braeckman *et al.* 2014). Hence, this species is considered an ideal model organism for studying the sediment-animal-interactions in a modified habitat (Reise *et al.* 2009). The habitat modifications of this ecosystem engineer result in an increased habitat complexity and heterogeneity, facilitating the evolution of a more diverse and abundant macrobenthic community (Rabaut *et al.* 2007; Toupoint *et al.* 2008).

Biogenic reefs, including *L. conchilega* reefs, are listed as Habitat 1170 under Annex I of the EC Habitats Directive EEC/92/43, and are hence important from a conservation point of view (Godet *et al.* 2008; Rabaut *et al.* 2009). Nevertheless, research on the structural and functional role of biogenic reefs, and ecosystem engineers in general, mostly focuses on one single ecosystem component at a time (*i.e.* macrobenthos, Rabaut *et al.* (2007); or fish, Rabaut *et al.* (2010)) and takes place on the local scale (*i.e.* the Belgian Part of the North Sea for Rabaut *et al.* (2007), Rabaut *et al.* (2010) and Rabaut *et al.* (2013)). To proceed towards the widespread implementation of conservation measures for biogenic reefs, understanding the general ecological function of the reefs, including their simultaneous effect on multiple ecological components and possible associated food web interactions, is of crucial importance. Additionally, in order to avoid merely local evidence on the importance of the reefs, a generalization of the outcome, and hence conducting research beyond the local scale, should be aimed at. In the case of *L. conchilega*, the impact of a reef is most elaborately studied regarding the associated macrobenthic community (Zühlke 2001; Rabaut *et al.* 2007; Van Hoey *et al.* 2008; De Smet *et al.* 2013). Furthermore, some top-down effects on meiofauna (Zühlke *et al.* 1998; Braeckman *et al.* 2011) and biogeochemical characteristics (Braeckman *et al.* 2010; Passarelli *et al.* 2012); and bottom-up effects on juvenile flatfish (Rabaut *et al.* 2010; Rabaut *et al.* 2013) and waders (Petersen and Exo 1999; De Smet *et al.* 2013) have been reported. All this suggests that *L. conchilega* reefs play a central role in the link between benthic, pelagic and air-borne parts of the intertidal food web. Nonetheless, rather little or no attention has been paid to the entire intertidal epibenthic (benthic organisms living on the surface of the sediment, such as most crabs, shrimp and starfish, (Baretta-Bekker *et al.* 1992)) and

hyperbenthic community (small animals living in the water layer close to the seabed, (Mees and Jones 1997)) associated with *L. conchilega* reefs.

This study took into account the entire range of benthic-pelagic components forming part of the intertidal *L. conchilega* reef and exceeded the local scale, by incorporating two different locations along the French coast characterized by different environmental settings. The following hypothesis were tested: (1) the *L. conchilega* reef does not affect the different components of the benthic community (*i.e.* macro-, epi-, and hyperbenthos); and (2) the reef effect, if any, is not affected by the local environmental characteristics of the reef area.

## 2. Material & Methods

### 2.1. Study area

The two sampling locations were selected based on the presence of a well-established intertidal *L. conchilega* reef and are located along the French side of the English Channel: (1) the bay of the Mont Saint-Michel (BMSM), a large-scale intertidal sand flat located in the Normand-Breton Gulf (48°39,70' N-01°37,41' W; Lower Normandy, France), and (2) Boulogne-sur-Mer (further referred to as Boulogne), a small-scale beach along the northern part of the English Channel (50°44,01'N-01°35,15'E; Northern France). The main *L. conchilega* reef of the BMSM is situated in the central part of the bay and in the lower section of the tidal flats, covering 25 000 ha. The large tidal flats result from the extreme megatidal regime (tidal range up to 15.5 m during spring tides) which dominates the BMSM (Larsonneur *et al.* 1994). Boulogne is characterized by a tidal range up to 7 m and in comparison to the BMSM, the beach of Boulogne is less pristine and sheltered by two harbour walls (Rabaut *et al.* 2008). The *L. conchilega* reef is situated in the lower intertidal and the majority is only exposed during extreme mean low water spring tide conditions.

### 2.2. Sampling design, sampling and laboratory treatment

Sampling took place in 2012, during spring (from 7<sup>th</sup> until 13<sup>th</sup> of March in the BMSM and from 22<sup>nd</sup> until 25<sup>th</sup> of March in Boulogne) and autumn (from 17<sup>th</sup> until 21<sup>st</sup> of September in BMSM and from 15<sup>th</sup> until 18<sup>th</sup> of October in Boulogne). To cover an adequate amount of reef heterogeneity, a *L.*

*conchilega* reef area of 100x100 m was defined at each location. In addition, a second 100x100 m sampling area (control), in the absence of any bioengineering species was defined. The bathymetric level between the reefs and their respective control areas was similar and the sampling areas were at least 300 m apart. At all sampling areas, several components of the soft-bottom assemblage were sampled simultaneously: water, sediment, macro-, epi-, and hyperbenthos.

Three water samples were taken during ebbing tide for the determination of suspended particulate matter (SPM, mg.L<sup>-1</sup>) and chlorophyll a (Chl *a*, µg.L<sup>-1</sup>) concentrations. For both SPM and Chl *a*, an appropriate subsample was filtered onto precombusted (450°C for 2h) and pre-weighed Whatman GF/F filters (47 mm) and subsequently stored at -80°C until analysis. Filters for Chl *a* were lyophilised and pigments were extracted in 90% acetone. Chl *a* concentrations of the supernatant were determined using HPLC (Gilson) analysis (Wright and Jeffrey 1997).

Within each sampling area, ten sediment samples were randomly taken during low tide with a core (Ø 3.6 cm) for sediment factors (median grain size and mud content) and the total amount of organic matter (TOM). Sediment grain size was analysed by means of a Malvern Mastersizer 2000; TOM was determined per sample by weighing the difference between the dry weight (48h by 60°C) and the weight after 2h by 500°C. The Chl *a* concentration (µg.g<sup>-1</sup> dry sediment) of the upper sediment layer was determined using HPLC (Gilson) analysis (as described above) and used as a proxy for the microphytobenthos (MPB) biomass (Jeffrey *et al.* 1997). *L. conchilega* densities were estimated by counting the tube tops with fringes on photographs of ten randomly placed metal frames (0.25 m<sup>2</sup>) (Ropert and Dauvin 2000; Van Hoey *et al.* 2006). Finally, per sampling area, ten macrobenthos samples were collected with an inox corer (Ø 12 cm, 40 cm deep), sieved through a 1-mm circular mesh size and fixed with a neutralized 8% formalin solution. In the laboratory, samples were rinsed and preserved using a neutralized 4% formalin solution with 0.01% Rose Bengal until processing. All macrobenthos was sorted, counted and identified to the lowest possible taxonomic level.

The lower water column (up to 40 cm) covering the sampling areas was sampled to study the epi- and hyperbenthic communities of the *L. conchilega* reef. Epibenthos was sampled with a 2 m beam trawl during daytime ebbing tide. The net was 3 m long, had a mesh size of 9x9 mm and was equipped with

a tickler-chain in the ground rope. Similarly, hyperbenthos was collected with a hyperbenthic sledge during daytime ebbing tide. The sledge consisted of a metal frame (100x40 cm) and was equipped with two identical nets: a lower and an upper net. Both nets were 3 m long and (at the mouth) 20 cm high with a mesh size of 1x1mm. The epi- and hyperbenthic devices were towed in the surf zone across the defined sampling area and parallel to the coastline for 100 m. In Boulogne, they were pulled by two persons, while in the BMSM a zodiac was used at a speed of one knot, due to the extreme tides and the extent of the bay. At least three epibenthos and three hyperbenthos replicates (trawls) were taken at each sampling area. Catches were fixed in a neutralized 8% formalin solution. In the laboratory, samples were stained with 0.01% Rose Bengal, rinsed, sorted and identified to the lowest possible taxonomic level. Because of the large content of three hyperbenthos Boulogne autumn samples, subsamples (20% of the total sample weight) were taken.

### 2.3. Data analysis

#### 2.3.1. Environmental variables

Since the assumptions of parametric statistical approaches were not fulfilled for none of the environmental variables (water SPM and Chl *a* concentrations; sediment grain size, mud content and TOM; MPB biomass), the effect of the presence of a *L. conchilega* reef on the selected environmental variables was explored with a permutational ANOVA (Permanova) in which Reef (reef versus control), Location (BMSM versus Boulogne) and Period (spring versus autumn) were fixed factors. The analysis was based on an Euclidean distance resemblance matrix and performed on untransformed data, except for TOM which was fourth-root transformed in order to meet homogeneity of dispersions (Anderson *et al.* 2008). In case a significant effect was found, pair-wise tests among all pairs of levels of the given factor(s) were carried out. Although Permanova makes no explicit assumptions regarding the distributions of the original variables, a test for the homogeneity of multivariate dispersions was ran, using the PERMDISP routine. Factors were considered significant at  $p < 0.05$  in all analyses. For mud content, MPB biomass, water SPM and Chl *a* concentrations the PERMDISP test was significant for some factors (even after transformation), indicating differences in dispersion. Therefore, prudence

is advised when interpreting the results and the relative sizes of the within and between-group resemblances deserve further attention (Anderson *et al.* 2008).

### 2.3.2. Macro-, epi-, and hyperbenthic community descriptors

Faunistic terms are used here as working definitions based on the efficiency of the sampling gear, following Beyst *et al.* (2001a; 2001b), resulting in a semi-artificial classification. For the macrobenthos, *L. conchilega* itself was excluded; as well as strictly hyper-, or epibenthic organisms (Appendix A). The remaining abundance data was standardised per m<sup>2</sup>. For the hyperbenthos, strictly macrobenthic, larger epibenthic and sessile organisms were removed from the dataset (Appendix B), while for the epibenthos, strictly macrobenthos and animals which were more efficiently caught with the hyperbenthic sledge (small sized crustaceans such as isopods and mysids; early postlarval fish and jellyfish) were excluded (Appendix C). Different developmental stages of decapods (zoea, megalopa and juveniles) were treated as different 'taxa', since they have a different ecology (Beyst *et al.* 2001a). Epi-, and hyperbenthic abundances were standardized per 1000m<sup>2</sup>. Univariate Permanova analyses were based on Euclidean distance resemblance matrices and performed on untransformed data; except for macrobenthic species abundance and epibenthic species richness which were fourth-root transformed in order to meet homogeneity of dispersions (Anderson *et al.* 2008). Prior to Permanova, analysis of similarity (one- way ANOSIM) based on Bray-Curtis resemblance matrices of untransformed data was used to test for (dis-)similarities in the hyperbenthic community between the lower and upper net. The same 3-factor Permanova design as for the environmental variables was used on the macro-, hyper-, and epibenthic community descriptors (species abundance  $N$ , species richness  $S$ , Shannon-Wiener diversity index  $H'$  and Pielou's evenness index  $J'$ ). In case a significant effect was found, pair-wise tests were carried out. Since our main interest is the effect of a *L. conchilega* reef on the associated communities, only significant results including the factor Reef are shown. All PERMDISP tests were significant for one or more factors, except for macrobenthic species abundance and  $H'$ ; epibenthic species richness,  $J'$  and  $H'$ ; and hyperbenthic species richness, species abundance and  $J'$ . Multivariate 3-factor Permanova analyses (see univariate analysis) were based on Bray-Curtis resemblance matrices of fourth-root transformed macro-, epi-, and hyperbenthos community

abundance data. According to a PERMDISP test, the Reef x Period and the Reef x Location interactions for the macrobenthic community and the factor Reef for the epibenthic community showed significant differences in dispersion. In addition, data were visualised by a Principal Coordinates Analysis (PCO)(Anderson *et al.* 2008). Based on Spearman correlations, only species of the macro-, epi-, and hyperbenthic community that correlated  $> 50\%$  with one of the first 2 PCO axes were plotted. Distance-based linear models (DistLM) was carried out to investigate the relationship between the benthic community and the environmental variables (Anderson *et al.* 2008). For the macrobenthic DistLM, all environmental variables (grain size, mud content, TOM, MPB, Chl *a* and SPM) and one biotic predictor variable (*L. conchilega* density) were used. In comparison to the macrobenthic community, 3 additional biotic predictor variables (macrobenthic *N*, *S* and *H'*) were used for the epi-, and hyperbenthic DistLMs. Macro-, epi-, and hyperbenthic abundance data was fourth-root transformed and a Bray-Curtis resemblance matrix was used. If necessary, environmental and biotic predictor variables were square-root or log transformed to avoid skewness. Variables were tested for multi-collinearity and redundant variables were removed from the analysis in case the correlation  $|r| \geq 0.95$  (Anderson *et al.* 2008). A significance level of  $p < 0.05$  was used in all tests. All statistical analyses were performed within PRIMERV6 with the PERMANOVA+ add-on software (Clarke and Gorely 2006; Anderson *et al.* 2008).

### 3. Results

#### 3.1. Environmental variables

Fine (125 – 250  $\mu\text{m}$ ) and medium (250 – 500  $\mu\text{m}$ ) sand were the major sediment fractions in all samples. Median grain size in the BMSM ranged from 196 to 324  $\mu\text{m}$ , while in Boulogne from 185 to 261  $\mu\text{m}$  (Table 1). A significant Reef x Location x Period effect for average median grain size was revealed (3-factor Permanova: pseudo-F = 5.27,  $p = 0.026$ ; Appendix D). However, differences due to Reef were only significant in the BMSM (pair-wise tests: reef < control in spring:  $p = 0.0001$ ; and reef < control in autumn  $p = 0.0002$ ). The average mud content (fractions < 63  $\mu\text{m}$ ; Table 1) was significantly affected by the Reef x Location interaction (3-factor Permanova: Pseudo-F = 11.80,  $p = 0.0001$ ; Appendix D). Pairwise tests showed a significant difference between the reef and control area

of the BMSM (reef > control:  $p = 0.0001$ ). Mean TOM content (Table 1) was shown to be significantly different due to the factors Reef (Permanova: Pseudo-F = 17.41,  $p = 0.0001$ ; reef > control; Appendix D), Location (Permanova: Pseudo-F = 55.94,  $p = 0.0001$ ; BMSM > Boulogne; Appendix D) and Period (Permanova: Pseudo-F = 6.44,  $p = 0.0081$ ; spring > autumn; Appendix D).

Mean microphytobenthos (MPB) biomass of the upper sediment layer (Table 1) was significantly affected by the interactions of Reef x Location (3-factor Permanova: Pseudo-F = 5.67,  $p = 0.0163$ ; Appendix D), and Reef x Period (3-factor Permanova: Pseudo-F = 8.74,  $p = 0.0025$ ; Appendix D). A pair-wise test for the Reef x Location interaction showed a significantly higher MPB biomass for the reef vs. control area of Boulogne ( $p = 0.0014$ ) but not for the BMSM, while a pair-wise test for the Reef x Period interaction showed a significantly higher MPB biomass for the reef vs. control area in spring ( $p = 0.0007$ ), but not in autumn. A 3-factor Permanova revealed a significant difference in mean SPM (Table 1) for Reef x Location (Pseudo-F = 16.86,  $p = 0.0012$ ; Appendix D), resulting from a significant difference between the reef and control area both in the BMSM (pair-wise test: reef > control:  $p = 0.0163$ ) and Boulogne (pair-wise test: reef < control:  $p = 0.03$ ). Finally, regardless of the location, the mean Chl *a* concentration of the water was observed to be substantially higher in spring samples compared to autumn samples (Table 1). The mean Chl *a* concentration was significantly affected by the Reef x Period interaction (3-factor Permanova: Pseudo-F = 4.88,  $p = 0.0375$ ; Appendix D), as a result of a significant difference in autumn (pair-wise test: reef < control:  $p = 0.0096$ ), and was significantly higher in the BMSM (3-factor Permanova; Location: Pseudo-F = 6.85,  $p = 0.01$ ).

### 3.2. Effect of Reef and location on the macrobenthic community

In total, 100 910 macrobenthic organisms belonging to 57 different taxa were sampled in the BMSM, of which 83 637 organisms (belonging to 44 taxa) in the reef area and 17 273 organisms (belonging to 34 taxa) in the control area. In Boulogne, 299 185 macrobenthic organisms were sampled (of which 294 548 in the reef area and 4 727 in the control area), belonging to 58 taxa (53 taxa in the reef area and 16 taxa in the control area). Mean *L. conchilega* density ( $\pm$  SE) in the BMSM reef was  $1\,724 \pm 292$  ind.m<sup>-2</sup> and  $5\,044 \pm 589$  ind.m<sup>-2</sup> in the Boulogne reef. Excluding *L. conchilega*, 96% of the remaining macrobenthos was classified in three major taxa: polychaetes (61%), amphipods (23.4%)

and bivalves (15.6%). The macrobenthic community in the BMSM was dominated by the bivalves *Cerastoderma edule* (39.5%) and *Macoma balthica* (13.3%), and the polychaete *Malmgreniella arenicolae* (6.8%). In Boulogne, the amphipod genus *Urothoe* (26%) and the polychaetes *Eumida sanguinea* (19.1%), *Pygospio elegans* (16.3%), *Heteromastus filiformis* (13.5%) and *Capitella sp.* (11.6%) were dominant. Permanova revealed that all community descriptors (Table 2) were significantly affected by the Reef x Location interaction (Appendix E). Pair-wise comparisons revealed a significantly higher macrobenthic abundance (Fig. 1) and species richness, and a significantly lower  $J'$  in reef areas compared to control areas, both in the BMSM and Boulogne (for all pair-wise tests:  $p = 0.0001$ ). Although significant differences between the reef and control area were detected for  $H'$  in Boulogne (pair-wise test: reef > control:  $p = 0.0001$ ), none could be detected for the BMSM (pair-wise test:  $p = 0.1249$ ). Seasonal variances of all calculated indices were negligible in comparison to variances as a result of Reef and/or Location, except for *L. conchilega* density.

Multivariate analyses revealed a significant interaction effect of Reef x Location (3-factor Permanova: Pseudo-F = 14.49,  $p = 0.0001$ ) and Reef x Period (3-factor Permanova: Pseudo-F = 3.40,  $p = 0.0041$ ) on the macrobenthic community. Differences between the *L. conchilega* reef and control areas were highly significant for the two locations and the two periods (all four pair-wise tests:  $p = 0.0001$ ). The PCO analysis (Fig. 2) showed a clear separation of reef samples vs. control samples. Moreover, the reef areas of the BMSM and Boulogne were clearly distinguishable from one another, while this was not the case for the control areas. PCO axis 1 explained 30.2 % of the total variation inherent in the resemblance matrix and separated reef samples and control samples. Besides, reef areas were characterized by a larger array of taxa compared to areas in the absence of *L. conchilega*. PCO axis 2 explained 17.9 % of the total variation and distinguished the locations, albeit not clearly for the control areas. The DistLM analysis showed that the variables *L. conchilega* density (15.1 %), mud content (9.0 %) and grain size (4.4 %) together explain 28.45 % of the variation in the macrobenthic community structure (Appendix F).

### 3.3. Effect of Reef and location on the epibenthic community

In the BMSM, 5 565 organisms belonging to 29 different taxa were sampled. The majority was sampled in the reef area (3 725 organisms; 21 taxa) in comparison to the control area (1 840 organisms; 24 taxa). The Boulogne sampling yielded 46 030 organisms (23 taxa), of which 44 005 organisms (17 taxa) were caught in the reef area and 2 025 organisms (16 taxa) in the control area. 94.6% of the epibenthos was confined to three taxonomic groups: *Crangon crangon* (89.8%), *Pomatoschistus spp.* (9%) and flatfish species (1.2%). The epibenthic community in the BMSM reef and control area was mainly dominated by the brown shrimp *Crangon crangon* (54.6% & 57.6% resp.) and by the gobies *Pomatoschistus lozanoi* (14.6% & 13.6% resp.) and *Pomatoschistus microps* (18.8% & 3% resp.). *Crangon crangon* was dominant in the epibenthic community of the Boulogne reef (90.5%) and control area (43.7%). In the latter area its dominance was complemented by the common shore-crab *Carcinus maenas* (23.5%) and *P. minutus* (21%). Species richness (Table 2) differed significantly between various combinations of Reef x Period (3-factor Permanova: Pseudo-F = 5.93,  $p = 0.0243$ ), which is the result of a significantly higher species richness in the reef vs. control area during spring (pair-wise test:  $p = 0.0049$ ). Mean epibenthic abundance (Fig. 3),  $J'$  and  $H'$  (Table 2) were significantly affected by the Reef x Location x Period interaction (Appendix E). In case of the mean epibenthic abundance, the significant effect was due to significant differences between the reef and control areas in the BMSM during spring (pair-wise test: reef > control:  $p = 0.032$ ) and in Boulogne during autumn (pair-wise test: reef > control:  $p = 0.0283$ ). For both  $J'$  and  $H'$ , the significant differences between the reef and control areas resulted from differences in Boulogne during autumn (pair-wise test  $J'$ : reef < control:  $p = 0.0273$ ; pair-wise test  $H'$ : reef < control:  $p = 0.0284$ ).

Multivariate analyses suggested that the epibenthic community differed among the Reef x Period interaction (3-factor Permanova: Pseudo-F = 2.36,  $p = 0.016$ ). Pair-wise tests showed that the epibenthic communities of the *L. conchilega* reef area and the control area differed both in spring ( $p = 0.0139$ ) and autumn ( $p = 0.0016$ ). Simultaneously, Permanova revealed highly significant community differences between the locations (*Location*: Pseudo-F = 17.56,  $p = 0.0001$ ). According to the PCO analysis, PCO axis 1 mainly showed a distinction between locations (explaining 34.6 % of the total variation), while PCO axis 2 separated spring samples and autumn samples (explaining 20.6 % of the

total variation) (Fig. 4). The DistLM analysis showed that the variables SPM (17 %), macrobenthic  $H'$  (11.8 %), macrobenthic  $N$  (21 %) and Chl  $a$  (9.8 %) together explain 59.6 % of the variation in the epibenthic community structure (Appendix F).

#### 3.4. Effect of Reef and location on the hyperbenthic community

In the BMSM, 134 020 organisms belonging to 100 different taxa were sampled. The majority was sampled in the reef area (93 610 organisms; 74 taxa) in comparison to the control area (40 410 organisms; 72 taxa). In Boulogne, 105 250 organisms belonging to 72 taxa were caught, of which 92 040 organisms (56 taxa) in the reef area and 13 210 (41 taxa) in the control area. 98.2% of the hyperbenthos could be classified in 5 taxonomic groups: mysidae (61.3%), shrimp (15.5%), amphipoda (13.9%), juvenile fish (6.9%) and juvenile crab (2.4%). The hyperbenthic community of the BMSM was mainly dominated by mysid shrimp: *Mesopodopsis slabberi* (72.3%) in the reef area; and *Schistomysis kervillei* (20.2%), *M. slabberi* (18.1%), *Schistomysis spiritus* (13%) and Mysidae sp. (12.7%) in the control area. In the Boulogne reef area, the hyperbenthic community was dominated by *Mesopodopsis slabberi* (27.5%), *Crangon crangon* juveniles (24.2%) and the amphipod *Nototropis swammerdamei* (17.9%); while dominated by sandeel *Ammodytes tobianus* juveniles (48.7%), *Crangon crangon* juveniles (16.1%) and Pleuronectiformes sp. juveniles (10.2%) in the control area. The hyperbenthic community was not significantly different between the lower and upper nets (one-way ANOSIM:  $p = 0.543$ ;  $R = 0.008$ ). Consequently, further statistical analyses were done excluding the factor Net. A 3-factor Permanova revealed that hyperbenthic abundance (Fig. 5) and  $J'$  (Table 2) are significantly affected by Reef ( $N$ : Pseudo-F = 6.48, reef > control:  $p = 0.0107$ ;  $J'$ : Pseudo-F = 4.93, reef < control:  $p = 0.0421$ ; Appendix E), while species richness (Table 2) was affected by Location (Pseudo-F = 30.11, BMSM > Boulogne:  $p = 0.0001$ ; Appendix E) and Period (Pseudo-F = 11.52, spring < autumn:  $p = 0.0048$ ; Appendix E).  $H'$  (Table 2) did not differ significantly for any of the factorial interactions.

Multivariate analyses revealed that the Reef x Location x Period interaction affects the hyperbenthic community (3-factor Permanova: Pseudo-F = 2.14,  $p = 0.0339$ ). However, only in Boulogne during spring the hyperbenthic community seemed to be significantly different between the *L. conchilega* reef

and the control area (pair-wise test:  $p = 0.0139$ ). According to the PCO analysis, PCO axis 1 explained 27.3 % of the total variation; distinguishing samples from the BSM and Boulogne (Fig. 6). Moreover, the hyperbenthic community of the BSM was characterized by a diverse species composition compared to Boulogne. PCO axis 2 explained 20 % of the total variation and separated spring and autumn samples, which was more pronounced for Boulogne. The DistLM analysis showed that the variables TOM (16.1 %), Chl *a* (15.5 %), SPM (18.6 %) and grain size (8.2 %) together explain 58.5 % of the variation in the hyperbenthic community structure (Appendix F).

#### 4. Discussion

##### 4.1. *Lanice conchilega* reef effect on the macro-, epi-, and hyperbenthic community

This study shows that the presence of *L. conchilega* reefs affect the associated macro-, epi-, and hyperbenthic communities. For all three investigated communities, the majority of the collected organisms was sampled in the reef (macrobenthos: 91 %; epibenthos: 81 %; hyperbenthos: 78.5 %), showing a more abundant benthic reef community compared to bare sands. Based on the proportion of animals in the reef versus control areas, the extent of the structuring effect seems to be most pronounced for the macrobenthos and least strong for the hyperbenthos. We suggest that this is due to the differential dependency of the three communities to the sea floor. The link between the benthic community and the sediment, where the effects of *L. conchilega* are most pronounced, is much more intimate for the macro- and epibenthos than for the hyperbenthos (Fig. 7). Moreover, the reefs predominantly affect the macrobenthic part of the benthos, which corroborates previous observations (Zühlke *et al.* 1998; Rabaut *et al.* 2007; Van Hoey *et al.* 2008; De Smet *et al.* 2013). The increased macrobenthic abundance, species richness and diversity is attributed to an increased habitat heterogeneity and shelter/refuge provision accomplished by the high tubeworm density. Similarly, epibenthic animals, which are considered to be free-living and highly mobile species in soft bottom assemblages, seem to select for *L. conchilega* reefs. Their mobile character enables them to actively move to and feed upon the macrobenthos within the biogenic habitat. As shown by the epibenthic DistLM analysis, the increased macrobenthic diversity ( $H'$ ) and abundance ( $N$ ) in the reef are in favor of the epibenthic community, as demonstrated before for *e.g.* (flat)fish (Rabaut *et al.* 2013). The

macrobenthic reef community in this study is characterized by a large array of taxa, of which bivalves (*Cerastoderma edule* and *Macoma balthica*), polychaetes (*Eumida sanguinea*) and amphipods (*Urothoe poseidonis*) are most abundant (Fig. 7). The positive effect of macrobenthos on higher trophic levels is in accordance with preliminary results of trophic relationships within *L. conchilega* reefs based on stable isotope and stomach content analysis (De Smet *et al.* unpublished). Similarly, polychaetes, amphipods and other small benthic animals are counted as a non-negligible part of the diet of macrocrustaceans such as the omnivorous brown shrimp, *Crangon crangon* (Boddeke *et al.* 1986; Oh *et al.* 2001). Abundances of this epibenthos species in the reef areas largely exceeded those from bare sand patches. In general, *C. crangon* is one of the most abundant epibenthic species in the European intertidal zones (Hostens 2000; Beyst *et al.* 2001b) and supports a large commercial fishery in northern European waters (Temming and Damm 2002). Hence, by fueling stocks of commercial fish species, *C. crangon* might be one of the most important inhabitants of the *L. conchilega* reef. Besides shrimp, *Pomatoschistus spp.* and flatfish species were notably represented in the reefs (Fig. 7). Several (commercial) benthic fish species were already shown to be attracted to biogenic habitats because they provide preferred prey species and/or act as refuges against predation (Kaiser *et al.* 1999; Rabaut *et al.* 2010; Chapman *et al.* 2012). Hyperbenthic communities were affected by the presence of the *L. conchilega* reefs. However, neither *L. conchilega* density nor macrobenthic species richness ( $S$ ), abundance ( $N$ ) or diversity ( $H'$ ) do contribute to the DistLM models explaining variation in the hyperbenthic assemblages. This suggests that the structuring effect of the reefs is indirect for the hyperbenthos. The high hyperbenthos abundances (dominated by mysida and to a lesser extent amphipods, juvenile fish and decapods, and shrimp excluding *C. crangon*) in the *L. conchilega* assemblages may be partly explained by their active migration to favorable environments (Dewicke *et al.* 2002). Highly motile hyperbenthos often reaches high densities in regions with a strong input of organic matter (Dauvin *et al.* 1994; Mees and Jones 1997). Therefore, the elevated amounts of TOM in the reefs, resulting from changes in the hydrodynamic regime due to the presence of *L. conchilega* tubes, were shown to sustain the high hyperbenthic abundances observed in our study. The increased *L. conchilega* density and hence the shelter against predation provided by the tubes, seems to be of a lesser importance to attract hyperbenthic animals. Notwithstanding their active, behavior-mediated

transport, the hyperbenthos is subjected to passive transport mechanisms as well (Mees and Jones 1997; Dewicke *et al.* 2002), limiting their reef selectivity.

In general, the macro – and epibenthic community are largely structured by biotic variables (due to tubeworm density and macrobenthic food availability respectively), while the hyperbenthos, which is the least dependent on the sea bed, is rather structured by environmental variables.

#### 4.2. The effect of the local environment on the macro-, epi-, and hyperbenthic community

At both locations, the macrobenthic reef samples are heavily clustered, which demonstrates that although the reef areas are very patchy, their species composition remains the same on a local spatial scale. On a larger scale, the magnitude of the reef effect on the macro-, epi-, and hyperbenthos seems to be influenced by the location of the reef. For the macro- and epibenthos, the differences in the community descriptors between a reef and control area were more pronounced for Boulogne than for the BMSM (except for the epibenthic species richness). The location effect is most likely driven by the difference in *L. conchilega* density between both sites, as shown by the DistLM analyses. The higher tubeworm densities in Boulogne ( $5\,044 \pm 589 \text{ ind.m}^{-2}$ ) compared to the BMSM ( $1\,724 \pm 292 \text{ ind.m}^{-2}$ ) can provide a larger and more secure settlement surface of larval and postlarval benthic organisms (Qian *et al.* 1999; Rabaut *et al.* 2007). Being characterized by a higher macrofaunal abundance and species diversity, high density *L. conchilega* reefs act as feeding grounds for more mobile epibenthic animals. Nevertheless, the high density reef of Boulogne was observed to have a lower mud content (silt + clay) and lower amounts of TOM compared to the lower density reef of the BMSM. This finding is in contradiction to the higher macrofaunal abundances in the Boulogne reef, which growth is believed to be promoted by the sedimentation of organic matter (Wieking and Kröncke 2005). Although the *L. conchilega* density is the most explaining predictor variable, the location effect is amplified by other location dependent environmental variables (e.g. grain size and Chl *a*).

Differences in the hyperbenthic community between locations were less pronounced and not attributable to the density of the tubeworm, but rather to environmental variables inherent to the location such as TOM, Chl *a* and SPM. Therefore, the hyperbenthos, which is dominated by mysids

and known to feed mainly on detritus, algae and zooplankton (Mauchline 1980), is largely structured by the availability of food.

The presence of the *L. conchilega* reef undoubtedly affects the abundances of all three investigated benthic communities and most notably the macrobenthic component. Moreover, our study shows that intertidal *L. conchilega* reefs do not only affect abundances and diversity but also the presence and relative contribution of species belonging to multiple trophic levels. As such, an altered predator-prey relationship in *L. conchilega* reefs versus bare sands can be presumed. Furthermore, the positive feedback of *L. conchilega* reefs on higher trophic levels of intertidal sandy beaches is shown to be applicable on locations with different environmental conditions. This outcome amplifies the current idea that *L. conchilega* reefs are important habitats under the Habitats Directive and might be crucial towards the implementation of widespread conservation measures in the future.

### **Acknowledgements**

The authors would like to acknowledge the marine station in Dinard for providing the speedboat Marphysa (CNRS). We thank Julien Guillaudeau, Jezabel Lamoureux (MNHN), Niels Viane and Bart Beuselinck for their assistance during the field campaigns in Boulogne and/or the bay of the Mont Saint-Michel. Dirk Van Gansbeke, Niels Viane, Bart Beuselinck, Liesbet Colson, Lynn Delgat, Sara Stempels and Sari Cogneau are acknowledged for their help during sample processing. Thanks to Renata Mamede da Silva Alves for help with GIS and Adobe Illustrator. We are grateful for the inspiring statistical comments of Ulrike Braeckman and Bob Clarke (PRIMER-E). We also thank the anonymous reviewers who improved earlier versions of the manuscript. Furthermore, this research has benefitted from a statistical consult with Ghent University FIRE (Fostering Innovative Research based on Evidence). Funding was provided by the Special Research Fund (BOF-GOA 01GA1911W), Ghent University, Belgium.

Appendix D. Three-factor univariate Permanova main and pair-wise tests results for the environmental variables. Reef (reef vs. control), Location (BMSM vs. Boulogne) and Period (spring vs. autumn) were fixed factors. Analyses were based on an Euclidian distance resemblance matrix and performed on untransformed data (except for the total organic matter, TOM, which was fourth-root transformed). Only significant results including the factor Reef are shown. In case of significant differences ( $p < 0.05$ )  $p$  values are in bold.

Appendix F. Sequential tests of the distance-based linear model (DistLM) analyses on the macro-, epi-, and hyperbenthic communities. Analyses were run on a Bray-Curtis resemblance matrix of fourth-root transformed data. Both environmental (grain size, mud content, TOM, MPB, Chl *a* and SPM) and biotic (*L. conchilega* density, macrobenthic *N*, *S* and *H'*) variables were included and (log or square-root) transformed if needed.
