Abstract :

High densities of the wood-boring bivalve *Xylophaga atlantica* colonized pine wood cubes in colonization devices deployed at 2279 m depth for 414 days (14 July 2007–31 August 2008) near hydrothermal vents at the Rainbow site on the Mid-Atlantic Ridge (36°13.7454'N/33°54.0513'W). Histological and biometric observations on specimens with shell lengths (SLs) of 0.5–4.2 mm revealed three cohorts in this dioecious population. The first cohort was dominated by mature females, each with an estimated fecundity of ~450 oocytes with a mean diameter of $28.0 \pm 3.9 \mu\text{m}$ (maximum diameter 40.0 μm); an intermediate cohort was a mix of males and females with SL at first maturity of $\leq 1.7 \text{ mm}$; the third cohort was exclusively morphologically distinct, mature, dwarf males, SL ~500 μm . These dwarf males were attached to the dorsal shell surfaces of females in the first cohort. The difference in the SL of Prodissoconch I (~60 μm) and Prodissoconch II (500–530 μm) confirmed planktotrophy. Based on their carbon and nitrogen stable isotope ratios, and a paedomorphic morphology suggesting they are ill-equipped to bore wood, it seems likely that the dwarf males are heterotrophic filter-feeders. Fluorescence in situ hybridization showed, however, that dwarf males hosted a few Gammaproteobacteria in their gills. The absence of a bacterial signal in the germ cells and developing oocytes of females implies that direct trans-ovarial inheritance of symbiotic bacteria does not occur in *X. atlantica*.

58 **Introduction**

59 The fragmented distribution of highly ephemeral wood-fall habitats in the deep sea (here defined as
60 > 200 m depth) depends on the initial introduction of wood into the marine environment (e.g. during
61 extreme weather events), the offshore transport of this wood by oceanographic processes and
62 ultimately, once waterlogged, the deposition of this wood within the deep ocean (Thiel and Gutow
63 2005; Canals et al. 2006; Tyler et al. 2007). Despite a patchy deep-sea distribution, naturally
64 occurring and artificially deployed wood logs are colonized at an astonishing speed by molluscan

65 wood-boring bivalves of the family Xylophagidae (Knudsen 1961; Turner 1973; Voight 2008;
66 Gaudron et al. 2010; Cunha et al. 2013; Romano et al. 2013; Amon et al. 2015). In a pioneering
67 study (Turner 1973), high densities of mature individuals of *Xylophaga* n. sp. were recorded in wood
68 panels after a short 3-month deployment at 1830 m in the Northwest Atlantic (39°46'N/70°41'W).
69 This study led her to hypothesize that xylophagid larvae were abundant, transported by bottom
70 currents and guided by an ability to detect wood over considerable distances, with the capacity to
71 delay metamorphosis in the absence of wood and to settle rapidly following appropriate
72 environmental cues. Culliney and Turner (1976) went on to confirm that pediveligers of *X. atlantica*
73 (from a shallow water population) in laboratory-based larval studies were indeed able to delay
74 metamorphosis for up to 6 months, indicating a potential to considerably extend the pelagic larval
75 duration (PLD) (see review on PLD, Hilário et al. 2015). Recent short-term colonization experiments
76 (10 d) carried out in the Mediterranean Sea at 1700 m (Gaudron et al. 2010) and at hydrothermal
77 vents on the Mid-Atlantic Ridge (2275 m, Gaudron unpublished), from which post-larval stages of
78 *Xylophaga* spp. were recovered, appear to confirm Turner's predictions. Haga and Kase (2013)
79 measured the relative size differences between the post-embryonic and post-settlement larval shells
80 of *X. supplicata* – i.e. the Prodissoconch I (PdI: ~40 µm) and the Prodissoconch II (PdII: ~310 µm;
81 shell that is deposited during pelagic larval dispersal) –and found that larvae were planktotrophic for
82 long periods spent in the water column, according to the criteria of Jablonski and Lutz (1983).

83 Only a few reproductive studies have been carried out on the genus *Xylophaga* (reviewed by
84 Voight 2015), describing a diversity of reproductive modes. There are contradictory findings for *X.*
85 *dorsalis*, with evidence for both protandric hermaphroditism (Purchon 1941) and dioecism (Tyler et
86 al. 2007). The latter mode was also identified in *X. depalmai* where simultaneous hermaphrodites
87 were observed occasionally (Tyler et al. 2007). In Haga and Kase (2013), many (though not all)
88 specimens of *X. supplicata* were identified as protandric, first developing as males and then changing
89 into females after temporary simultaneous hermaphroditism. However, a number of small,
90 paedomorphic specimens attached to the shells of larger females were ultimately found to be dwarf
91 males and not brooded juveniles, as had previously been suggested (Knudsen 1961; Turner 2002).
92 Extrapolating from this misidentification, Haga and Kase (2013) surmised that some or all
93 *Xylophaga* spp. known to harbor brooded juveniles (19 of the 53 species described), could instead be
94 carrying dwarf males. Using histology, Ockelmann and Dinesen (2011) identified functional dwarf
95 males in *Xyloredo ingolfia* but misidentified the species according to Haga and Kase (2013), because
96 it was actually *Xylophaga clenchi*. The relatively frequent occurrences of this phenotype in deep-sea
97 wood-boring species are considered by some authors to be an adaptation to a relative scarcity of
98 wood substrata in deeper waters.

99 Wood falls are a locally important input of energy in an otherwise nutrient-depleted deep sea.
100 Various processes contribute to wood-fall degradation. One of these is xylotrophy. Teredinid and
101 xylophagaid families capable of burrowing into wood do so by repeated rotations of their specialized
102 shells which are adorned with rasping denticles (Voight 2015). The wood fragments are then
103 swallowed and stored within a caecum in the foregut of the bivalve (Distel et al. 2011). Though
104 many wood-boring bivalve species are believed to host gill-associated symbionts, only the
105 Gammaproteobacteria (e.g. *Teredinibacter turnerae*) found in the gills of teredinid shipworms have
106 been well-categorised metabolically (Waterbury et al. 1983; Distel et al. 2002a, b; O'Connor et al.
107 2014). These Gammaproteobacteria can perform both cellulolysis and fix nitrogen. In the
108 xylophaguids, Distel and Roberts (1998) first identified bacterial symbionts within the gills of
109 *Xylophaga atlantica* and *X. washingtona*. Based on 16S rRNA high-throughput sequencing,
110 Fagervold et al. (2014) have since identified bacterial OTUs (Operational Taxonomic Units) within
111 the gills of *Xylophaga* spp. that resemble those identified in shipworms. However, the exact location
112 of these bacteria within host tissues, their abundance and their activity remain undetermined.

113 *Xylophaga atlantica* were collected from 2279 m depth on the Mid-Atlantic Ridge and those
114 found carrying potential dwarf males were investigated. We conducted a comprehensive analysis of
115 their reproduction and nutrition. We tried to answer several questions in this study: 1) Are the
116 biology and ecology of this deep *X. atlantica* population similar to that described for shallow-water
117 *X. atlantica*? To answer this we examined gametogenesis, fecundity, growth rate, size at first
118 maturity and larval shell dimensions (PdI and II), using histology, scanning electron microscopy and
119 image analysis; 2) What could have driven dwarfism in this *X. atlantica* population? 3) Being ill-
120 equipped to bore wood, do dwarf males host symbiotic bacteria in their gills and is there evidence of
121 symbiont assimilation? To test this, we used Fluorescence in situ Hybridization (FISH) to look for
122 bacterial symbionts within gill filaments, and employed stable isotope analyses ($\delta^{13}\text{C}$ and $\delta^{15}\text{N}$) to
123 identify whether xylotrophy might contribute to host nutrition; 4) Is there any evidence for maternal
124 transmission of bacterial symbionts during oogenesis? FISH was applied to reproductive tissues to
125 confirm whether putative bacterial symbionts were present within oocytes at various stages of their
126 development within the female acini.

127

128 **Materials and methods**

129 Collection and identification

130 Wood-boring bivalves were collected from numerous 2 cm-sided pine wood cubes housed in a single
131 **CHEMECOLI** (**CHEM**osynthetic **E**cosystem **CO**lonization by **L**arval **I**nvertebrates) colonization

132 device which was deployed on 14 July 2007 for 414 d on the Mid-Atlantic Ridge at the Rainbow
133 hydrothermal vent field (36°13.7454'N and 33°54.0513'W), at 2279-m depth near some small vent
134 chimneys (Online resource 1). The device contained 87 cubes for a total wood volume of 1.539 dm³.
135 Once on board, cubes were randomly selected from the bottom, middle and top of the device, and
136 fixed in different fixatives in a cold room. Specimens from cubes fixed in 4% buffered formaldehyde
137 in twice-filtered seawater (TFSW) were used for taxonomy. Specimens from cubes fixed in 95%
138 ethanol were used for biometry and those frozen at -20°C were used for stable isotope analyses.
139 Specimens from cubes fixed in 4% buffered formaldehyde in TFSW for 4 h at 4°C, rinsed three
140 times in TFSW and then transferred into 50/50 Ethanol/TFSW were used for both Fluorescence in
141 situ hybridization (FISH) and for reproductive histology, following the same protocol as Gaudron et
142 al. (2012). Wood cubes were dissected aseptically with sterile razor blades in order to collect all
143 wood-boring bivalves. Specimens were identified morphologically based on descriptions by Turner
144 (2002).

145 DNA was extracted from 13 large individuals and 15 dwarf males using the QiaQuick
146 Dneasy Kit (Qiagen, USA). Partial sequences of the gene encoding 28S rRNA were amplified by
147 PCR using primers 28S-C1 ACCCGCTGAATTTAAGCAT and 28S-
148 C2TGAACTCTCTCTTCAAAGTTCTTTTC, as described in Williams et al. (2004). Sequences were
149 compared with GenBank using the Blast tool (Altschul 1997) and deposited to GenBank with
150 accession KU684449 (one larger specimen) and KU684450 (one dwarf male).

151

152 Haematoxylin / Eosin staining and Fluorescence in situ Hybridization (FISH)

153 A total of 16 *Xylophaga atlantica* (Online resource 1) of various sizes (1.7–4.2 mm shell lengths,
154 SL) from the smallest to the largest individuals identified from sorting (except dwarf males) were
155 measured using an Olympus SZX12 binocular equipped with SPOT software before being dissected.
156 Tissues were rinsed in butan-1-ol and Histoclear (Euromedex Ltd.) and embedded in Paraffin
157 Embedding Wax (melting point 52°C). The soft tissues (bivalves without shell) were cut into 8 µm-
158 thick sections using a microtome (Microtome Finesse 325, Thermo Fisher Scientific) and deposited
159 on SuperFrost Plus slides (Euromedex Ltd.). A standard haematoxylin/eosin (HE) staining protocol
160 (Gaudron et al. 2012) was used on one in every ten slides and observations were performed using an
161 Olympus BX61 light microscope (Olympus, Japan) equipped with ImagePro software. The sex was
162 identified in these 16 specimens. Oocyte diameters were measured in 7 female specimens and partial
163 fecundity was estimated by counting the total number of fully-grown oocytes within all acini seen in
164 histological sections of four females.

165 Potential dwarf males (SL < 500 μm , $n = 5$) were blotted dry and infiltrated (8 x 30-min
166 infiltrations) in a gelatine capsule (size 00, Electron Microscopy Sciences, UK) filled with LR-White
167 resin (London Resin Company, UK), transferred to a fresh resin-filled gelatine capsule, orientated
168 appropriately, capped, and polymerised at 55°C (20 h minimum). Gelatine was then removed with
169 hand-hot water. Resin blocks were wet-sectioned (glass knife) on a Leica EM Ultra Cut R
170 Ultramicrotome (Germany) to thicknesses of 350 nm–1 μm , deposited on Superfrost-plus slides, and
171 stained in Toluidine Blue while others were unstained for FISH.

172 FISH was employed on the non-stained slides of both large specimens and potential dwarf
173 males to reveal the presence of possible symbiotic bacteria in gills and female gametes following the
174 protocol of Gaudron et al. (2012). Due to the small size of the bivalves, a cross-section of the entire
175 individual, including the digestive tract, acini with gametes, and the gill could be visualized on most
176 slides. The paraffin wax was removed using a serial gradient of ethanol and Histoclear prior to FISH.
177 The LR-White slide-mounted sections were only rehydrated in phosphate buffered saline (PBS 1x).
178 FISH was performed using Cy3- and Cy5-labeled probes as described previously (Duperron et al.
179 2005) with a hybridization buffer containing 30% formamide. Probes Gam-42 (5'-
180 GCCTTCCCACATCGTTT-3'; Manz et al. 1992), targeting the 16S rRNA (small subunit) of most
181 Gammaproteobacteria, EUB-338 targeting most Eubacteria (5'-GCTGCCTCCCGTAGGAGT-3';
182 Amann et al. 1990) and NON-338, a control for non-specific binding (5'-
183 ACTCCTACGGGAGGCAGC-3'; Wallner et al. 1993) were used. After washing, slides were
184 mounted in Slow-Fade Gold (Invitrogen) containing DAPI, which stains nucleic acids. Fluorescence
185 microscopy was performed using an Olympus BX61 light microscope (Olympus, Japan).

186

187 Size-distribution, bivalve density and growth rate

188 SLs of 100 large borers and 68 dwarf males were measured with an Olympus SZX12 binocular
189 microscope equipped with SPOT software. The protocol followed that of Romano et al. (2013),
190 using the Bhattacharya method and the specific routine in FISAT II package (FAO 2002) to identify
191 each *Xylophaga atlantica* cohort that recruited into the CHEMECOLI during the 414-d deployment.
192 SL frequency distributions in 0.25-mm SL intervals were used to accommodate all individuals in this
193 population, including the dwarf males.

194 The relative density of individuals was estimated by counting the number of wood-borers
195 recovered from a stratified, random subsample of 15 cubes from the top, middle and bottom of the
196 CHEMECOLI (5 cubes zone⁻¹). Minimal mean growth rate was estimated by subtracting the mean
197 SL of PdII from the computed mean SL of the first cohort from FISAT II, dividing the result by the
198 number of days of deployment, minus 10 d (404 d); post-larval stages of *X. atlantica* had already

199 colonized an identical, short-term, 10-d deployment (Gaudron unpublished data) at the same site
200 (Rainbow 2275m; 36°13.7553N and 33° 54.11W).SLs of PdII were measured in randomly selected
201 individuals ($n = 5$) in each cohort. Mean SL for each cohort were compared using a student test
202 (MINITAB v.15).

203

204 Stable isotope analyses

205 Frozen wood-boring bivalve females ($n = 3$) bearing dwarf males (pool of 30 individuals) were
206 identified under a dissecting microscope and dissected to remove the shell when possible. Frozen
207 wood cubes ($n = 3$) from CHEMECOLI were first sliced into pieces with a sterile scalpel, then rinsed
208 in distilled water, and finally screened under a dissecting microscope to check for the presence of
209 metazoan material (tissue, faeces, eggs and larvae). Of these, bivalve tissues (autonomous and dwarf
210 males), pieces of wood and one amphinomid polychaete (control) were rinsed in distilled water and
211 then dried (2 d, 60 °C). Some dried subsamples of female wood-borer tissues and a pool of whole
212 dwarf males were treated with 1 N HCL (~3 h) to remove inorganic carbon and then rinsed with
213 distilled water.

214 1 mg (± 0.1 mg) of dried bivalve, polychaete tissues or wood pieces were analysed using a
215 CHN elemental analyser (EuroVector, Milan, Italy) for particulate organic carbon (POC) and
216 particulate nitrogen (PN) in order to calculate their C/N atomic ratio (Cat/Nat). The resultant gas
217 from the elemental analysis was introduced into a GV IsoPrime (UK) stable isotope mass
218 spectrometer at Iso-Analytical (Crewe, UK). Values of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ were determined and
219 expressed as relative per-mil (‰) differences between samples and Pee Dee Belemnite (PDB) for
220 carbon and air for nitrogen according to the following equation:

$$221 \quad \delta(X) = \left[\left(\frac{R_{\text{sample}}}{R_{\text{standard}}} \right) - 1 \right] * 1000$$

222 where X (‰) is ^{13}C and ^{15}N abundance and R is the $^{13}\text{C}/^{12}\text{C}$ and $^{15}\text{N}/^{14}\text{N}$ ratios.

223

224 Scanning Electron Microscopy (SEM)

225 The dwarf males and the autonomous wood-boring females were dehydrated using an ethanol series
226 and critical-point dried, then coated with gold before observations with a SEM (Cambridge S260 at
227 15 kV). PdI was observed and measured. The internal anatomy of a dwarf male was observed.

228

229 **Results**

230 Identification

231 Identification of wood borers was based on taxonomically-relevant features of the inhalant and
232 exhalant siphons, the shape of the mesoplax (Online resource 1) and the posterior adductor scar,
233 which all matched the description of *Xylophaga atlantica* (Turner 2002). The 28S rRNA partial
234 sequences of all specimens (including putative dwarf males, see Fig. 1b, c) were identical (base to
235 base). Compared with GenBank, each returned sequences with 98% similarity scores to five 28S
236 rRNA sequences attributed to *Xylophaga atlantica* deposited by Romano et al. (2014). Figure 1b
237 shows dwarf males attached ventrally by the byssus threads on the dorsal side of an autonomous
238 female (Online resource 2). Dwarf males did not have the denticles on their shells needed to bore
239 and rasp wood (Fig. 1c; Online resource 2). The SL of the PdI was $\sim 60\mu\text{m}$ (Online resource 2).
240 Dwarf males had mature spermatozoa (Online resource 2). No dissoconch deposition (adult shell)
241 was observed in dwarf males, despite the presence of mature spermatozoa and a ligament, which
242 indicated that metamorphosis into adults had occurred (Online resource 2). Thus dwarf male SL, 540
243 $\pm 2.2 \mu\text{m}$ ($n = 68$), essentially represented their SL at settlement (i.e. PdII).

244

245 Size structure of the population

246 The SL frequency distributions were trimodal (Online resource 3), but there were only two true
247 cohorts since dwarf males lacked adult dissoconch shell despite being sexually mature (Online
248 resource 2). The cohort with the individuals with the greatest SL ($3.4 \pm 0.5 \text{ mm}$) were mostly large
249 females bearing dwarf males (Online resource 3), and the eight specimens in this size range used in
250 histology were all females (Fig. 2). The intermediate cohort (Online resource 3) had a mean SL of
251 $2.6 \pm 0.4 \text{ mm}$: the sex ratio for the eight specimens used in histology in this size range was 1:1 (Fig.
252 3). The remaining cohort with the smallest SLs had a mean SL of $0.6 \pm 0.1 \text{ mm}$, and was composed
253 exclusively of dwarf males examined using both SEM (Online resource 2) and histology (Fig. 4).
254 The density of all *Xylophaga atlantica* (including dwarf males) was estimated at 6853 individuals
255 dm^{-3} . The minimal shell growth rate was estimated at $7 \mu\text{m d}^{-1}$ for the first cohort (Online resource
256 4). Mean SL of PdII for the three cohorts were not significantly different using a *t*-test (Cohort 1: 500
257 $\pm 10 \mu\text{m}$; Cohort 2: $530 \pm 30 \mu\text{m}$; cohort 3: $530 \pm 30 \mu\text{m}$).

258

259 Gametogenesis, fecundity, size at first maturity and spawning behaviour

260 All specimens examined using SEM or HE staining of histological sections had mature gametes, so
261 no immature specimens were observed. Wood-boring females ($n = 12$) carrying mature oocytes were
262 1.7–4.2 mm SL. Non-dwarf wood-boring males ($n = 4$) and dwarf males, both carried all stages of
263 gametes (spermatogonia to mature spermatozooids), and were 1.7–2.3 mm SL and 0.48–0.58 mm SL
264 respectively. Partial fecundity was estimated at $450 \pm 130 \text{ oocytes female}^{-1}$ ($n = 4$). Mean oocyte

265 diameter was $28.0 \pm 3.9 \mu\text{m}$ ($n = 7$) for mature females in the first cohort (Fig. 2a, c) with a
266 maximum diameter of $40 \mu\text{m}$. A few mature oocytes in Prophase I (unfertilized), similar to those of
267 the first-cohort wood-boring females, were found in the gill chambers of two second-cohort males
268 (Fig. 2a, c). These spawned oocytes were probably captured following their release by a female,
269 suggesting that spawning was occurring when the colonization device was retrieved. There was no
270 evidence of hermaphroditism.

271

272 Symbiotic bacteria

273 In females and non-dwarf males, gill filaments were occupied by dense populations of symbiotic
274 bacteria in gill cells devoid of cilia (Fig. 2b, d; Fig. 3b). Depending on sectioning angle and region
275 (see HE sections [Fig. 3c; Fig. 3a]), the abundance of ciliated versus bacterium-loaded gill epithelial
276 cells varied but no quantification was attempted. Signals from the Gammaproteobacteria- and the
277 Eubacteria-targeting probes almost fully overlapped in both sexes, indicating that gill-associated
278 bacteria were predominantly Gammaproteobacteria. Histological sections of female gametes at
279 different stages of oogenesis were available, their nuclei stained with DAPI (Fig. 2b). Germ cells
280 gave strong DAPI blue signals (as did the nuclei of gill-filament epithelial cells), allowing the
281 boundaries of acini to be discerned, within which fully-grown vitellogenic oocytes were packed (Fig.
282 2a). No bacterial signal was ever found on, or inside germ cells and fully-grown vitellogenic oocytes,
283 where the unambiguous bacterial signal in gill tissue served as a positive control (Fig. 2b). Bacteria
284 are therefore believed to be absent from reproductive tissues in these *X. atlantica*.

285 In dwarf males, gill filaments were less numerous and much smaller (Fig. 4b). Nevertheless,
286 unambiguous Gammaproteobacteria FISH signals were detected in association with the non-ciliated
287 abfrontal regions of gill filaments (white arrow in Fig. 4c). Visually, bacterial densities were lower
288 than those in larger specimens. Bacteria appeared to be extracellular, but higher resolution would be
289 needed to confirm this.

290

291 Wood-based diet and trophic level

292 Stable isotope analyses performed on female wood-borers yielded $\delta^{13}\text{C}$ values of $\sim 22\text{‰}$ close to the
293 $\delta^{13}\text{C}$ values of the wood itself ($\sim 23\text{‰}$) (Table 1). Dwarf male tissues were more enriched in ^{13}C
294 ($\sim 20\text{‰}$), resembling values obtained for the amphinomid polychaete control (Table 1). Despite the
295 paucity of nitrogen within the wood itself (C/N ~ 160 ; Table 1) C/N values of the overall fauna were
296 3–5 (Table 1). The $\delta^{15}\text{N}$ values ($\sim 4\text{‰}$; Table 1) of the females were just at the upper limit of
297 primary producers in food webs (Minagawa and Wada 1984), while $\delta^{15}\text{N}$ values ($\sim 6.5\text{‰}$; Table 1) of
298 the dwarf males resembled nitrogen stable-isotope signatures corresponding to primary consumers

299 (Minagawa and Wada 1984). For comparison, amphinomid polychaetes, usually seen as predators,
300 had $\delta^{15}\text{N}$ values of $\sim 8\text{‰}$ (Table 1). This reflects the lowest limit for secondary consumers within
301 food webs (Minagawa and Wada 1984).

302

303 **Discussion**

304 Wood-boring bivalve specimens in this study were identified as *Xylophaga atlantica* Richards 1942
305 based on morphology (Turner 2002) and 28S rRNA sequences with a 98% similarity to sequences of
306 *X. atlantica* in Genbank. The 28S rRNA sequences of large females in the present study matched
307 (100% similarity) with 28S rRNA sequences of dwarf males, which confirms that individuals belong
308 to the same species. *Xylophaga atlantica* has previously been collected in the Western Atlantic at
309 depths of 15–1242 m (Turner 2002) and more recently, *X. atlantica* ('morphotypes C, D and E') was
310 collected from 900–2000 m in the Western Mediterranean Sea and Eastern Atlantic (Romano et al.
311 2013; 2014; Online resource 4). However, none of these studies reported the presence of dwarf
312 males. One may wonder what could have induced this phenotypic plasticity in morphology and
313 reproductive strategy.

314

315 Traits of *Xylophaga atlantica* from deep and shallow populations

316 Specimens of *X. atlantica* in the current study were gonochoristic; there was no evidence of sex
317 change through a hermaphroditic phase. The mature oocytes ($\sim 40\ \mu\text{m}$) in this study are very similar
318 to those of a shallow population of *X. atlantica* ($45\ \mu\text{m}$, Culliney and Turner 1976). Large females
319 and their associated dwarf males both carried mature gametes, while spawned oocytes were observed
320 within the pallial cavity of non-dwarf males and female specimens. This could indicate spawning
321 synchronicity within this xylophagaid population at the time of sampling (end of August 2008), and
322 suggests that some instances of fertilization might occur within the pallial cavity of one, or the other
323 parent. At the end of the 414-d deployment three cohorts of veligers had recruited (or two, if we
324 exclude dwarf males). Shallow-water *X. atlantica* has been shown to recruit seasonally (Berg et al.
325 1987). Culliney and Turner (1976) found ripe *X. atlantica* in late summer, and suggested
326 metamorphosis and settlement occurred from autumn to winter. Our data cannot detect whether
327 seasonality played a role in structuring size-frequency distributions in the MAR population.

328 Fecundity and size (age) at first maturity in xylophaguids have only been recorded previously
329 in *X. depalmai* from colonization devices deployed at 500 m (Tyler et al. 2007; Online resource 4).
330 In that study, fecundity was stated to be 'high' but no data were provided. Gametogenesis was
331 already occurring in specimens collected from 59-d colonization experiments, with size at first

332 maturity > 2 mm SL (Tyler et al. 2007; Table 1). In the present study, the size at first maturity was ≤
333 1.7 mm SL for non-dwarf males and females (Online resource 4). Dwarf males had SL at first
334 maturity of ≤ 0.5 mm almost immediately after settlement. It is difficult to classify the fecundity as
335 low, moderate, or high in this study (~ 450 oocytesfemale⁻¹), given the paucity of other data.
336 Fecundity in the opportunistic gastropod *Cocculina rathnuni*, colonizing deep-sea wood substrates,
337 was only 40 oocytes female⁻¹ (Young et al. 2013), who argued that low fecundity was still
338 compatible with opportunism, as larval predation pressure in the deep sea is likely less than in
339 shallow water. It is not clear whether this is true for larvae arriving at reducing habitats, such as
340 sunken wood, where faunal densities are much higher. However, only one specimen of a wood-fall
341 species known to feed on xylophagaid larvae (Ockelmann and Dinesen 2011) was collected from the
342 CHEMECOLI (see Rodrigues et al. 2015), the small larvivorous mussel *Idas argenteus*. Wood-fall
343 habitats are highly ephemeral. Tyler et al. (2007) argued that biological traits such as the early
344 reproductive development of *X. depalmai*, typically rare in deep-sea organisms, may represent
345 adaptations to ephemeral reducing habitats (e.g. hydrothermal vents, whale falls and wood falls).
346 Similar hypotheses have since been proposed for other molluscs that colonize wood, which are also
347 small at first maturity. These include the bathymodiolin mussels *Idas modiolaeformis* (2.35 mm SL,
348 Laming et al. 2014) and *I. simpsoni* (1.8 mm SL, Génio et al. 2015), and several wood-colonizing
349 limpet species (e.g. *Cocculina rathbuni*: <1.5 mm SL, Young et al. 2013).

350 In our study, the estimated growth rate of *X. atlantica* (7 μm d⁻¹) was relatively low when
351 compared with previous wood colonization experiments (Online resource 4). This may reflect spatial
352 constraints imposed by the high densities of individuals collected in a low temperature habitat.
353 Physical crowding has been proposed as contributing to unexpectedly low growth rates in shallow-
354 water *X. atlantica* (Romey et al. 1994; Online resource 4) and in deep-water, dense populations of *X.*
355 *alexisi* (Voight and Segonzac 2012; Online resource 4). These authors argued that at low population
356 densities, *X. alexisi* might have much higher potential growth rates.

357

358 Larval biology of a deep *Xylophaga atlantica* population

359 The SL of the PdII for the three cohorts (~ 500–530 μm), and the small post-embryonic PdI of the
360 earliest veliger (SL ~ 60 μm), provide insights into the planktotrophic larval mode and its duration
361 (Jablonski and Lutz 1983). The size of the PdII measured in this study is nearly twice that recorded
362 for larvae of laboratory-reared, shallow-water *X. atlantica* (Culliney and Turner 1976). This suggests
363 that veligers of the wood-borers recovered within CHEMECOLIs at 2279 m, have probably spent an
364 extended period of time in the water column. Such extended periods may be an adaptation to very
365 fragmented habitat distributions. This hypothesis was proposed for *X. alexisi* larvae from an abyssal-

366 plain population (4626 m) as a means of surviving long periods in the plankton (Voight and
367 Segonzac 2012). The relatively cool (~ 4°C) water temperature in the deep Atlantic Ocean may
368 lengthen PLDs, as lower temperatures are likely to induce lower metabolic rates.

369 PdII SLs in *X. atlantica* mirror sizes recorded previously in the cold-seep bathymodiolin
370 mussels *Idas modiolaeformis* and '*Bathymodiolus*' *childressi*, where PLDs of up to 5 and 13 months
371 respectively have been demonstrated (Gaudron et al. 2012; Arellano et al. 2014). Under favourable
372 oceanographic transport conditions, extended PLD could explain the broad geographical distribution
373 of *X. atlantica*, spanning the Eastern Atlantic, into the Western Atlantic, and to the Western
374 Mediterranean (Romano et al. 2014). *Xylophaga atlantica* may thus be considered an ampho-Atlantic
375 candidate species with a potential for long-distance dispersal comparable to that documented in some
376 *Bathymodiolus* species (Olu et al. 2010).

377
378 Epigenetic factors influencing sex-determination in *Xylophaga atlantica*?

379 The existence of large females and dwarf males in *X. atlantica* suggests a kind of epigenetic sex-
380 determination in this species, rather than complete genetic sex regulation. There may be
381 environmental drivers similar those in other metazoans, such as food availability, population density
382 and temperature (e.g. Santerre et al. 2013). In the present study, two epigenetic or 'proximate' factors
383 may apply: food availability and the diminution of the spatial niche. Consider the following scenario:
384 at the beginning of the colonization experiment in 2007, deployed wood represented nascent habitat
385 for settling wood-borer larvae, where optimal food availability favoured a female bias in the sex-
386 ratio (first cohort) as seen in other bivalves where oogenesis requires a considerable energy
387 investment (Chávez-Villalba et al. 2011). During the course of the 414-d deployment, the wood was
388 progressively consumed by this first cohort so food and space availability decreased with time. New
389 colonists that arrived and settled (second and third cohorts) shifted the population towards a male
390 bias, spermatogenesis having a lower metabolic demand (Chávez-Villalba et al. 2011). In this
391 scenario, the initial epigenetic factor driving sex-determination is food availability, favouring
392 females. The second, a smaller spatial niche, selects for non-dwarf males and ultimately, dwarfism
393 with larvae settling directly on female shells. Romano et al. (2014) did not find dwarf males in their
394 samples of *X. atlantica*. However, their colonization experiments used pieces of wood ten times
395 bigger than those in the current study, with wood-borer densities 60 times lower than those described
396 here, so there were no constraints on food or space.

397 Male dwarfism has evolved in species with small population sizes and in which the female is
398 sedentary or hard to find, such as the echiurian, *Bonellia viridis* (Berec et al. 2005). Haga and Kase
399 (2013) recorded a similar trend in wood-associated *X. applicata* with low population densities,

400 where the direct association of females with dwarf males would increase fertilisation success, while
401 dwarfism was argued to compensate for a rarity of wood logs (resource limiting). Voight (2015)
402 pointed out that dwarf males offer a dioecious strategy that minimizes crowding and resource
403 consumption. In the opportunistic polychaete, *Osedax* spp., which colonize decomposing whale
404 carcasses (another sulfidic deep-sea organic-fall habitat), most males are dwarves with a high density
405 of female bone-eating worms (Rouse et al. 2004). Occurrence of dwarf males in *X. atlantica* and
406 *Osedax* spp. seems to be a convergence that may reflect similar evolutionary constraints acting on
407 these species in habitats that share many characteristics (ephemeral existence, patchiness, rarity, but
408 with the potential to sustain a very productive population locally, despite resource limitations).

409

410 Xylotrophy and symbiosis in wood-boring adults versus associated dwarf males of *Xylophaga*
411 *atlantica*

412 Xylotrophy was examined in shallow-water *X. atlantica* (recovered from oak in lobster traps at 100-
413 m depth in the Western Atlantic), but it is not clear whether Gammaproteobacteria in the gills of
414 *Xylophaga* spp. play any role in cellulolytic (synthesis of cellulase enzyme) or/and nitrogen-fixing
415 activities (Distel and Roberts 1997). In our study, the shape and sculpture of xylophagaid shells (e.g.
416 such as in cohorts 1 and 2) allows them to physically bore wood, with the potential to assimilate the
417 pulp with the aid of hypothesized cellulolytic symbiotic bacteria (metazoans are rarely able to
418 produce cellulase). Stable isotope values suggest that large specimens (1st cohort) had a diet based on
419 direct wood consumption, with ~ 1‰ fractionation (DeNiro and Epstein 1978) of the ¹³C between
420 the wood and bivalve tissues. The C/N (~160) of the wood is a consequence of low nitrogen levels, a
421 feature common to most sunken-wood habitats (Nishimoto et al. 2009; Duperron et al. 2013). That
422 means that xylotrophic metazoans need a separate source of nitrogen, and symbiosis with nitrogen-
423 fixing bacteria may be one alternative. Gammaproteobacteria were very abundant in the gills of large
424 *X. atlantica* specimens in this study but were rare by comparison in the gills of dwarf males. To date,
425 the role of these putative gill bacterial symbionts in both dwarf males and full-sized specimens has
426 yet to be confirmed.

427 Stable carbon isotopes (~ 20‰) recorded in the dwarf males did not reflect the consumption
428 of wood in the current study. $\delta^{15}\text{N}$ ratios (Table 1) were more in line with the levels of primary
429 consumers in a classical food web and much higher than those of large specimens (Minagawa and
430 Wada 1984). Fagervold et al. (2014) described specific bacterial communities found in association
431 with the faecal pellets of *Xylophaga* spp., which accumulate within their burrows. Given the high
432 densities of *X. atlantica* in this study, it is likely that the resulting faecal matter and by-products
433 generated through burrowing would have formed a component of the dwarf males' diet. Thus, not

434 only do the dwarf males retain paedomorphic traits, but they are likely predominantly heterotrophic
435 filter-feeders. Unfortunately stable isotope analyses in the current study did not include the
436 associated detritus, so the exact source of nutrition in dwarf males cannot be confirmed.

437

438 Bacterial transmission in *Xylophaga atlantica*

439 The absence of Gammaproteobacteria in oocytes suggests that bacterial symbionts of *X. atlantica* are
440 not transmitted directly from the parent organism during gametogenesis or prior to spawning. The
441 presence of a low number of bacteria in dwarf males measuring ~ 500 μm SL indicates that symbiont
442 acquisition had already occurred at this stage in this sex-related phenotype. Since shell development
443 following metamorphosis cannot be defined, it remains unclear whether acquisition occurred prior to,
444 during, or after settlement, as reported for some Bathymodiolinae mussels (Laming et al. 2014;
445 2015). The potential for horizontal bacterial transmission may be supported by recent 454-
446 pyrosequencing analyses of the bacterial communities associated with our pine wood cubes, which
447 identified close relatives of shipworm symbionts (Szafranski et al. 2015). It is possible that free-
448 living forms of these symbionts (or the same symbionts living in other proximal hosts) may be
449 acquired directly from the environment. Although it is possible that mature oocytes acquire bacteria
450 while entrained within the bacteria-loaded gill filaments of females and large males (i.e. before or
451 around the time of fertilization), no bacteria were found attached to oocytes in the pallial cavity of
452 specimens from the current study.

453

454 **Conclusion**

455 Here we have presented evidence that higher population density in *Xylophaga atlantica* may be
456 accompanied by shifts in reproductive mode, probably in response to epigenetic influences. Rapid
457 settlement, moderate fecundity and small size at first maturity may be adaptations to the ephemeral
458 and patchy nature of wood-fall habitats, while male dwarfism, an extreme form of sexual
459 dimorphism, is believed to be an adaptation to the inherently finite nutritional and spatial resources
460 available. The apparent disparity between PLDs of shallow- and deep-water *X. atlantica* likely
461 relates to the relative paucity of suitable habitats in the deep sea leading to long larval dispersal. The
462 small sizes and different nutrition of dwarf males permit the opportunistic use of a unique spatial
463 niche. This adaptation allows *X. atlantica* populations to persist through resource partitioning,
464 despite their finite availability. Regarding symbiosis we confirm that large specimens of *X. atlantica*
465 host Gammaproteobacteria within their gills but with no occurrence in germ lines, which likely rules

466 out trans-ovarial inheritance, suggesting environmental bacterial transmission is the principal mode
467 for symbiont transmission.

468

469 **Acknowledgements**

470 Authors would like to thank the people who have deployed and recovered the CHEMECOLIs:
471 Delphine Cottin and Amandine Nunes Jorge. We are grateful to chief scientists, captains and crews
472 of RVs *Pourquoi pas?* and *L'Atalante*, and teams operating ROVs *Victor 6000* (Ifremer, France) and
473 submersible *Nautilus* (Ifremer, France) during the cruises MOMARDREAM-07 and
474 MOMARDEAM-08. Sample collection and construction of the CHEMECOLIs were funded by
475 CHEMECO (European Sciences Foundation (ESF)/Eurocores/EURODEEP/0001/2007). Analyses
476 and interpretation of data were supported by HERMIONE European Commission (FP7/2007-2013-
477 n° 226354), University of Pierre and Marie Curie and Institut Universitaire de France. S. Laming
478 was co-funded by a MARES PhD grant (FPA2011-0016), a post-doctoral grant HERMIONE EC
479 (FP7/2007-2013-n° 226354). T. Haga was partially funded by a Grant-in-Aid for JSPS fellows
480 (#198300 and #237855). We would like to thank C. Romano for interesting scientific exchanges on
481 the biology and ecology of wood-boring bivalves. We would like to thank J. Voight on scientific
482 exchanges regarding taxonomy. We would like to thank also V. Bazin (IFR83, UPMC) for a great
483 experience with the scanning electron microscopy, N. Léger for her help with some of the
484 preparation of in situ hybridization, and C. Rodrigues for running the PCRs and the two molecular
485 sequence analyses.

486

487 **Compliance with Ethical Standards**

488 This study was funded by both European Sciences Foundation (ESF)/Eurocores/EURODEEP/0001/2007)
489 and by HERMIONE European Commission (FP7/2007-2013-n° 226354). All authors declare that they
490 have no conflict of interest. All applicable international, national, and/or institutional guidelines for
491 the care and use of animals were followed.

716 **Table 1** Mean stable C and N isotope values (\pm SD) and C/N ratios for female and associated dwarf male *Xylophaga atlantica*

717 collected after 414 d at 2279 m depth at Mid-Atlantic Ridge. Values for one co-occurring polychaete added as positive control.

Samples	<i>n</i>	$\delta^{13}\text{C}$	$\delta^{15}\text{N}$	C/N
Wood	3	-23.1 (\pm 0.1)	-	159.6 (\pm 17.3)
Female autonomous wood-borers	3	-	4.6 (\pm 0.5)	5.3 (\pm 0.3)
Female autonomous wood-borers acidified	3	-21.7 (\pm 0.3)	-	-
Dwarf males acidified	30	-20.2	6.4	3.8
	(pool)			
Amphinomid polychaete	1	-19.9	8.0	4.4

719

720 **Figure captions**

721

722 **Fig. 1** SEMs of *Xylophaga atlantica* females bearing dwarf males. a) Prodissoconch I (PdI)
723 with edge marked by arrow (scale bar 50 μ m); b) female with attached dwarf males
724 (outlined) (scale bar 1 mm); c) dwarf males from b) magnified (scale bar 500 μ m)

725

726 **Fig. 2** Microscopic images of autonomous wood-boring females *Xylophaga atlantica* (~3
727 mm SL). a) transverse section of tissues stained with haematoxylin/eosin (HE) highlighting
728 female reproductive features, mature oocytes on right and gill on left, with possible
729 spawned oocytes (scale bar 500 μ m); inset shows mature oocytes at higher magnification
730 (scale bar 50 μ m); b) fluorescence in situ hybridization (FISH) image showing bright green
731 gill (probe EUB-338 [Cy-3]) and DAPI-stained nuclei of gill filament and germinal cells. Note
732 absence of bacterial signal in acini in germinal cells and oocytes compared to positive
733 control in gill (arrow) (scale 50 μ m); c) HE-stained section showing gill filament with pink
734 ciliated region (arrow) and non-ciliated region (purple); also showing oocytes, germinal cells
735 and spawned oocytes (scale bar 50 μ m); d) FISH image showing overlapping EUB-338
736 (Cy-3; green) and Gam-42 (Cy-5; red) staining (white arrow) and DAPI-stained nuclei in gill
737 (blue); note bacterial signal in non-ciliated gill region (scale bar 50 μ m); be?, spawned
738 oocyte; gc, germinal cell; gl, gill filament; ov, mature oocyte

739

740 **Fig. 3** Microscopic images of autonomous wood-boring males *Xylophaga atlantica* (~2 mm
741 SL). a) transverse section of tissues stained with haematoxylin/eosin (HE) highlighting
742 male reproductive features and gill filament of two types: ciliated (blue arrow) and non-
743 ciliated (red arrow); b) fluorescence in situ hybridization image showing overlapping EUB-
744 338 (Cy-3; red) and Gam-42 (Cy-5; green) yielding few bright dots (white arrow) and DAPI-
745 stained nuclei in gill (blue arrow). Scale bars 50 μ m; spc, spermatocyte; gl, gill filament

746

747 **Fig. 4** Microscopic images of dwarf males *Xylophaga atlantica* (~0.5 mm SL). a) longitudinal
748 serial section of tissues stained with haematoxylin/eosin highlighting male reproductive
749 features (scale bar 200 μ m); b) and c) high magnification of a closely similar LR-White
750 semi-thin sections (300 nm); b) section stained with Toluidine blue showing two gill
751 filaments with ciliated region (arrow) (scale bar 15 μ m); c) section hybridized by
752 fluorescence, where Gam-42 (Cy-3) yield some bright green dots in gill (arrow) and DAPI-

753 stained nuclei (scale bar 15 μm); ft, foot; gl, gill filament; spc, spermatocyte; sg,
754 spermatogonia; msp, mature spermatozoa; re, rectum; te, testis; pa, posterior adductor
755 muscle
