SUPPLEMENTARY MATERIAL

Nile basin study area and Sampling

The Nile River is located in north-eastern Africa and is the longest river in the world. It flows over 6700 km, over 31° of latitude, and has a watershed area of 3,000,000 km^2 [1]. The Nile watershed is essentially composed of two main catchments, both of silicate lithology[2]: the Ethiopian highlands, or traps, are mainly composed of basaltic volcanic rocks and are drained by the Blue Nile and the Atbara rivers; the Equatorial craton is mainly composed of gneiss and granulite rock and is drained by the Bahr el Jabel River. This river joins the Sobat River to form the White Nile[3].

At its mouth, the Nile River has a unimodal discharge curve over a year, with summer floods essentially linked to the seasonal monsoonal circulation over the Ethiopian highland sources[2]. Thus, the tropical climate of the Nile Basin is marked by African monsoon precipitation fluctuation. The seasonal change in monsoon precipitation in the Nile Basin is controlled by the convergence of winds from both hemispheres in the InterTropical Convergence Zone (ITCZ). Much of the rainfall over North-East Africa originates in the tropical Atlantic and southern/western Indian Ocean[4,5]. Mean annual precipitation greater than 3.2 mm/day was recorded by the Tropical Rainfall Measuring Mission at Lake Tana for the period 1998-2010[6]. At present, the monsoon occurs during the summer in Northern hemisphere, and the location of ITCZ is linked to the maximal insolation and oscillates north-south during the year. In the past, because long-term changes in the insolation maxima are modulated by changes in the Earth's precessional and obliquity cycles, the north-south migration of the African monsoonal rain belt followed the precessional cycles, with further northward ITCZ penetration during precessional minima[7]. High summer insolation in the early and mid-Holocene enhanced the thermal contrast between land and sea, producing higher rainfall than at present across North Africa, leading to the African Humid Period (AHP) between ~15 and 6 ka[6]. The AHP was evidenced in several sedimentary records[8,9] and mostly concerned the Ethiopian Traps region[10,11].

The MS27PT core was collected in 2004 during the Mediflux MIMES oceanographic cruise, in the Nile deep-sea-fan. The core was collected on along the continental slope at a depth of 1389 meters, from a non-channelized slope located 90km outward from the mouth of the Rosetta Nile branch[10,12]. The ability of this sediment core to monitor past hydrology and weathering changes in the Nile basin has been demonstrated in several sedimentology and geochemistry studies[13,14].

50   The core site is located adjacent to Rosetta river outflow, resulting in high accumulation rates

51   of terrigenous sediment at the site. Detailed bathymetric and high resolution seismic profiles

52   (eight oceanographic cruises[15]) demonstrated that the Rosetta branch has been active since 115

53   ka and that this western part of the delta has continuously received sediments from the Nile

54   River[12,13,16]. The sediment loads of each tributary have a distinct Nd isotopic composition

55   reflecting the geology of the catchments. Thus, temporal changes in both Nd signature and

56   sedimentation rate have allowed reconstructing changes in the terrigenous contribution in

57   relation to the north-south oscillation of rain belt[10,12–14].

58   The influence of the sea-level rise on the nature and the rates of sedimentation has already been

59   investigated in the MS27PT core[10]. The Nile continental shelf is about 30 km wide, with a shelf

60   edge located around 200m water depth (Rouillard, 2010). The post-glacial sea-level rise that

61   started around 20 kyrs with the MeltWater Pulse-1A (MWP-1A started 14,650 years ago and

62   ended before 14,130 years ago, coeval with the Bølling warming[17]. During the LGM, global

63   sea level was lowered by about 120 m, allowing direct connection between the Rosetta fluvial

64   mouth and the Rosetta turbidite system. As sea-level rise proceeded, the distance between the

65   canyon head and the main source of clastic sediments (the Nile estuary mouth) progressively

66   increased, to reach a maximum around 11.5-8 ka, when the shoreline was situated about 5-50

67   km landward of its present-day position (Stanley & Warne, 1993). As a result, if the distance

68   from the fluvial outlet to the shelf edge was the dominant controlling parameter, one could

69   expect higher sedimentation rates during the LGM along the Rosetta deep-sea fan

70   compared to the last deglacial period and the Holocene. This is not the case. In the same way,

71   [18] have studied more than 105 cores or sections distributed all along the Nile delta for the last

72   12,000 years. They conclude that Nilotic hydrology and particle flux are the main driver of

73   sedimentation rate variations.

74   The MS27PT core is characterized by continuous hemipelagic sedimentation over 7m (100

75   kyr). The present study focuses on the uppermost part of this sediment sequence (433cm), which

76   covers the last 32,000 years but exclude the last 3,000 years, potentially impacted by anthropic

77   activity. The published age models for the period studied are based on 22 AMS[14]C dates[10,13]

78   (Table S3). The age models as deduced from radiocarbon dating were calibrated to calendar

79   ages using the CALIB 7.0 program[19] and were corrected for a marine reservoir age difference

80   of 400 years for the Holocene, 560 years for the Bølling/Allerød and 800 years during the

81   deglaciation[20].

82

83   *Heinrich Events*

84   Rapid climate changes are associated with the Dansgaard–Oeschger (D-O) cycles or Heinrich

85   Stadia (HS) and are superimposed on the longer-term orbital climate trends[21,22]. Among them,

86   Heinrich events are recorded at the end of coldest stadial periods of the D-O cycle in the North

87   Atlantic Ocean and were accompanied by massive iceberg formation and extension of the sea

88   ice in North Atlantic[21,22]. Such disturbances of the hydrological conditions of surface waters

89   reduced deep water formation and thus modified Atlantic meridional overturning

90   circulation[23,24]. In tropical Africa, the impact of these events is still under debate but they are

91   expressed as the dustiest periods of the last glacial due to rapid increases in aridity and wind

92   strength in the Sahel[25,26].

Figure S3: *Mineralogical composition of the clay-sized fraction estimated by XRD as a function of time[14] and the lithium concentration in the clay fraction (black, this study). The pink bar corresponds to the mean value and uncertainties of lithium concentrations determined for clay samples collected in rivers of the Ethiopian traps, and submitted to the same physical and chemical protocol (Bastian et al., in prep).*
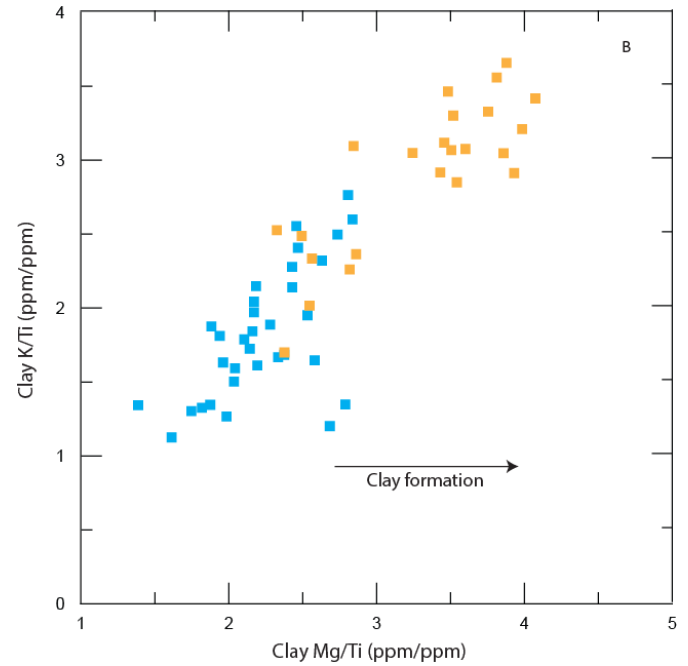

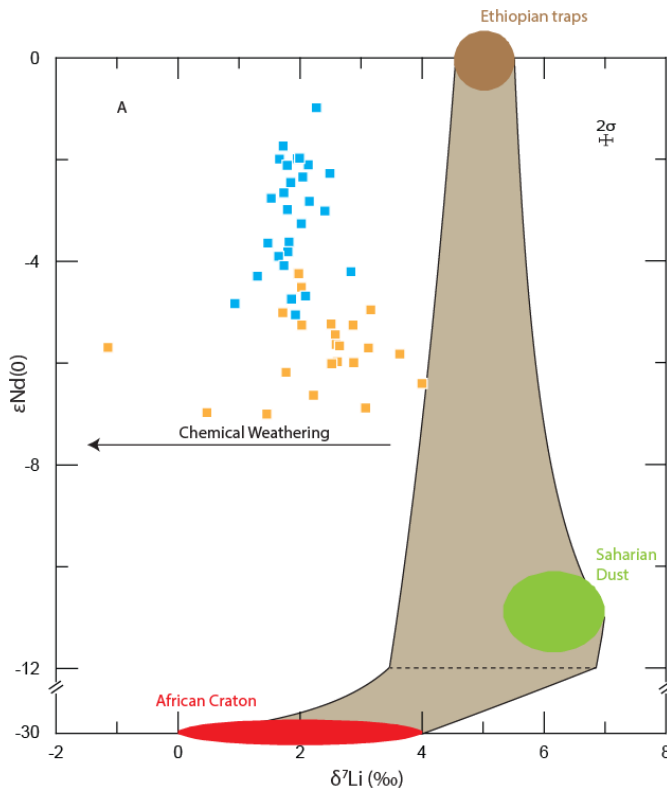

Figure S4: *(A) Clay lithium isotope composition as a function of clay neodymium isotope composition (MS27PT). The brown zone corresponds to the mixing zone for source rocks from the Ethiopian Traps, the African craton and the Saharan Dust (based on measured values (Table S1) and published average values for each endmember). The Saharan dust samples have been collected in the Libyan desert by Francis Grousset and consists mostly in quartz and carbonate grains (pers. comm.)[13]. The average d7Li value is 6.2±0.8‰ and average Li content is 2.2 ppm +/- 0.5ppm. The Ethiopian traps samples have been collected by Raphael Pik. Their average d7Li value is 5.0±0.5‰ with a Li content of 13.9ppm +/- 0.8 ppm. Clay δ^7Li are systematically enriched in ^6Li compared to fresh source rocks due to isotope fractionation during the clay formation process; (B) Clay K/Ti ratios as a function of clay Mg/Ti (MS27PT). The blue squares and orange squares correspond to humid and arid periods, respectively.*

Modeling Li isotopes

All published studies indicate significant lithium isotopic fractionation during secondary phase formation, in particular clay formation. This isotopic fractionation is always in favor of the light isotope (^6Li) and does not depend on the clay type[27]. In contrast, rock or mineral leaching is not associated with significant isotope fractionation at low temperature. Several recent studies have modeled the behavior of Li isotopes at the scale of a watershed or of a continent according to the following equations[27–31]:

$$F_{lea}^{Li}\delta_{lea} = F_{sp}^{Li}\delta_{sp} + F_{riv}^{Li}\delta_{riv} \qquad \text{equation (1)}$$

8

136

$$\delta_{sp} = \delta_{riv} - \Delta_{land} \qquad \text{equation (2)}$$

138

$$\delta_{lea} = \delta_{BR} \qquad \text{equation (3)}$$

140

$$\delta_{sp} = \frac{\Delta_{land}}{F_{lea}^{Li}/F_{sp}^{Li}} + \delta_{BR} - \Delta_{land} \qquad \text{equation (4)}$$

142

where F_{lea}^{Li}, F_{sp}^{Li}, and F_{riv}^{Li} are the flux of lithium during dissolution, in the secondary phase and in the river water, respectively, and δ_{lea}, δ_{sp}, δ_{riv} and δ_{BR} are the Li isotopic signature of the dissolved phase, the secondary phase, the river water and the bedrock, respectively. This model corresponds to a mass balance for lithium, such that, the Li released by the dissolution/leaching of the source rocks (F_{lea}^{Li}) is either incorporated into secondary minerals during their neoformation or released into the rivers, as shown in the box model in Figure S5. F_{lea}^{Li} and F_{sp}^{Li} depend on Li concentrations of the bedrock and the clays respectively, as well as dissolution rates and clay neoformation rates. Bedrock leaching is assumed to be isotopically congruent while clay neoformation fractionate Li isotopes (Δ_{land})[29,30]. This model is similar as the one developed by[29] which describes a conceptual model of alteration in the weathering zone and apply it to several isotope systems (e.g. Li, Mg, Ca, Si). The mass balance written for Li in equation (1) implies that the dissolved Li inventory and isotope composition are at steady state, which is likely to be true beyond a certain timescale related to the water residence time in the system. Equation (1) does not necessarily imply a soil "steady-state", as defined by several authors[29,32] as a balance between physical denudation and soil production by chemical erosion (constant soil thickness). Indeed, if soil thickness is increasing, due to low physical erosion and more neoformation, then more Li is immobilized into the weathering profile (in clays or secondary phases), and less Li is released into the river and if soil thickness is decreasing, more Li is released into rivers. Theoretical modeling curves are reported in Figure S5 for various clay-water isotope fractionation factors. As shown in this graph, during humid periods, the clay δ^7Li values (δ_{sp}) measured in the MS27PT core are in general low and homogeneous. This is consistent with the modelling and is best explained by a high F_{lea}^{Li} /F_{sp}^{Li} ratio and a low clay-

9

165   water isotope fractionation factor. During arid periods, the clay δ^7Li values (δ_{sp}) are much

166   more variable, increasing to higher values at specific times such as during the LGM. According

167   to the model, this corresponds to lower F_{lea}^{Li} /F_{sp}^{Li} ratios. When the F_{lea}^{Li} /F_{sp}^{Li} ratio is low, the

168   slope of the curve is steeper, and therefore clay δ^7Li values are more sensitive to small variations

169   in the alteration regime (F_{lea}/F_{sp}). In contrast, during humid periods (blue rectangles),

170   fluctuations in the alteration regime do not affect significantly the clay δ^7Li values. This is

171   consistent with the differences in the variability of our data between humid and arid periods

172   (see text for more details).

173

174

175

176
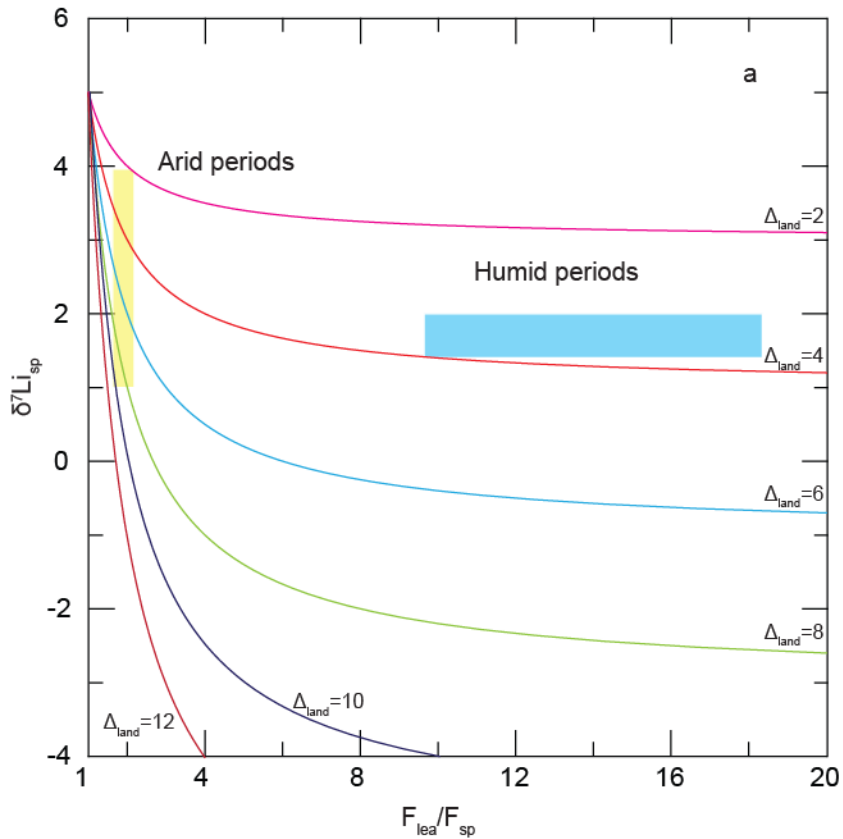

Figure S5: *a) Theoretical curves of δ^7Li_{sp} (δ^7Li value of secondary phases) as a function of F_{lea}/F_{sp}, where F_{lea} and F_{sp} are the Li flux corresponding to the dissolution of the source rock, and the flux of Li incorporated into secondary phase, respectively. Δ_{land} is the clay-water isotope fractionation. The yellow and blue shaded fields represent the range of clay δ^7Li values determined for the arid and humid periods, respectively. Their x-axis positions have been adjusted arbitrarily in order to illustrate the fact that, for a single isotope fractionation factor, a small range of clay $\delta7Li$ value, as exhibited during humid periods, is expected at high F_{lea}^{Li}/F_{sp}^{Li} values, while a larger range correspond to lower ratios. It also illustrates why during humid periods, large variations of F_{lea}^{Li}/F_{sp}^{Li}, ratio does not impact significantly the clay $\delta7Li$ value. In contrast, during arid periods, small variations of dissolution / precipitation rates result in significant clay $\delta7Li$ variations. b) Conceptual view of lithium fluxes taken into account in the modelling.*

Table S3: Radiocarbon chronology of core MS27PT[10]. Radiocarbon dating was performed at the
Laboratoire de Mesure du Carbone 14-Saclay (Paris, France) by the national facility in the framework
of INSU ARTEMIS call-for-proposal.
