Abstract. The temperature dependence of planktonic metabolism in the subtropical North Atlantic Ocean was assessed on the basis of measurements of gross primary production (GPP), community respiration (CR) and net community production (NCP), as well as experimental assessments of the response of CR to temperature manipulations. Metabolic rates were measured at 68 stations along three consecutive longitudinal transects completed during the Malaspina 2010 Expedition, in three different seasons. Temperature gradients were observed in depth and at basin and seasonal scale. The results showed seasonal variability in the metabolic rates, the highest rates being observed during the spring transect. The overall mean integrated GPP/CR ratio was 1.39 ± 0.27 decreasing from winter to summer, and the NCP for the subtropical North Atlantic Ocean during the cruises exhibits net autotrophy ($NCP > 0$) in about two-thirds (66 %) of the total sampled communities. Also, we reported the activation energies describing the temperature dependence of planktonic community metabolism, which was generally higher for CR than for GPP in the subtropical North Atlantic Ocean, as the metabolic theory of ecology predicts. Furthermore, we made a comparison of activation energies describing the responses to in situ temperature in the field

($E_{aCR} = 1.64 \pm 0.36$ eV) and those derived experimentally by temperature manipulations ($E_{aCR} = 1.45 \pm 0.6$ eV), which showed great consistency.

1 Introduction

The metabolic status of plankton communities is a fundamental property controlling the role of plankton communities in the ocean's carbon budget (Duarte et al., 2011, 2013). In particular, net community production (NCP), the difference between gross primary production (GPP) and community respiration (CR), determines whether plankton communities act as CO₂ sinks (autotrophic communities, $NCP > 0$) or CO₂ sources (heterotrophic communities, $NCP < 0$).

Recent analyses suggest that seawater temperature is a driver of plankton community metabolism (Regaudie-de-Gioux and Duarte, 2012), consistent with the metabolic theory of ecology (MTE, Gillooly et al., 2001; Brown et al., 2004), which predicts that both GPP and CR should increase with increasing temperature. MTE also expects that the activation energy (E_a) for respiration should be higher than for photosynthesis (Harris et al., 2006), as confirmed by

observations (López-Urrutia et al., 2006; Regaudie-de-Gioux and Duarte, 2012). Hence, plankton respiration rates are expected to increase faster with ocean warming than production rates. Consequently, ocean warming should lead to a weakening of the CO₂ uptake by ocean biota, and may lead to a possible positive feedback in the carbon global budget (Duarte et al., 2012, 2013).

Resolving the temperature dependence of planktonic community metabolism is fundamental to predict the future role of plankton in the carbon budget of a warmer ocean. However, research on ocean planktonic community metabolism is still limited spatially and temporally, with measurements focused on restricted areas such as the NE Atlantic Ocean, the eastern Arctic Ocean, the Southern Ocean and the Mediterranean Sea (Robinson and Williams, 2005; Regaudie-de-Gioux and Duarte, 2013). Even in the North Atlantic Basin, the most intensively studied area of the world's ocean, there is a paucity of estimates of net community metabolism in the western basin.

The North Atlantic Ocean plays an important role as a sink of atmospheric CO₂ (Sabine et al., 2004). However, it has been warming since the 1950s and its heat content has been increasing faster than the mean ocean rate (0.3 W m^{-2}), exceeding 8.0 W m^{-2} in the midlatitudes of the northwestern basin (Levitus et al., 2000, 2005). In addition, the subtropical North Atlantic Ocean shows a strong longitudinal and latitudinal temperature gradient, increasing from northwest Africa to northeast America, mainly due to influence from the Gulf Stream and North Atlantic Current (Marshall et al., 2001). This temperature gradient suggests that metabolic rates may vary spatially and that the current warming trend may affect planktonic communities differentially in the western and eastern basins of the North Atlantic Ocean, which experience different thermal regimes.

Here we assess the seasonal and regional variability of plankton metabolic rates in the subtropical North Atlantic Ocean. We do so on the basis of near-zonal cruises conducted along three seasons (Leg 1 in winter, Leg 2 in spring and Leg 3 during summer) in 2011. We also assess the thermal control on plankton metabolic rates, based on the in situ incubations and experimental temperature manipulations to examine the temperature dependence of community respiration rates.

2 Materials and methods

2.1 Sampling site and study area

The study was conducted in the framework of the Malaspina 2010 Expedition, a circumnavigation project that included three zonal cruises along the subtropical North Atlantic Ocean, encompassing a latitudinal range spanning from 12.4° N to 41.6° N and a large longitudinal variation from -79.2° E to -14.7° E (Fig. 1). The first cruise (Leg 1) was conducted on board Spanish R/V *Sarmiento de Gamboa*,

Figure 1. Map showing the stations occupied in Leg 1–winter (black circles), Leg 2–spring (white circles) and Leg 3–summer (white squares) during the Malaspina 2010 Expedition and the Longhurst Provinces crossed in the study.

sailing from the Canary Islands (Spain) to Florida (USA) along the 24° N parallel between 28 January and 9 March 2011, during the winter season. The second cruise (Leg 2) was also conducted on board Spanish R/V *Sarmiento de Gamboa*, which sailed from Santo Domingo (Dominican Republic) to Vigo (Spain) from 23 March to 8 April, during spring of 2011. The third and last cruise (Leg 3) was carried out on board Spanish R/V *Hespérides* sailing from Cartagena de Indias (Colombia) to Cartagena (Spain) during the summer of 2011, between 20 June and 10 July.

The three cruises included stations within five of the different biogeographical provinces described by Longhurst (Longhurst, 1998, 2007). Sampled stations were mostly concentrated in 3 provinces: the North Atlantic Subtropical Gyre Province East (NASE or NAST-E), including 4 stations in winter, 3 in spring and 7 in summer; the North Atlantic Subtropical Gyre Province West (NASW) with 7 stations in winter and 6 in spring; and the North Atlantic Tropical Gyre Province (NATR), with 23 stations in winter, 3 in spring and 8 stations in summer. The data set also included stations in the Caribbean Province (CARB) with one station in spring and five during summer; only one station was sampled within the North West Coastal Atlantic Shelves Province (NWCS) during the winter cruise (Table 3, Fig. 2).

Total concentration of chlorophyll *a* (Chl *a*), for spring and summer cruises was determined fluorometrically (following Yentsch and Menzel, 1963) by acetone extraction of chlorophyll *a* on the cells retained in GF/F filters after filtering 200–500 mL samples (Estrada, 2012). Chlorophyll *a* on cruise 1 in the winter was estimated from calibrated CTD fluorescence data ($R^2 = 0.92$, $p < 0.001$).

2.2 Community metabolism

Metabolic rates of the planktonic communities were measured at 35, 13 and 20 stations in Leg 1 (winter), Leg 2 (spring) and Leg 3 (summer), respectively, yielding a total of 68 stations (Fig. 1). During the three cruises seawater was

sampled at three different depths within the photic layer: the deep chlorophyll maximum (DCM, 114.1 ± 4.1 m), which receives, on average, 1 % of the incident irradiance; surface waters (4.5 ± 2.5 m); and an intermediate depth (43.1 ± 2.5 m) between surface and DCM, receiving 20 % of the incident radiation on the surface. Both DCM and intermediate depths were sampled using a Rosette sampler system fitted with a calibrated Sea-Bird SBE 9 CTD and 12 L Niskin bottles. Surface waters were sampled manually with a 30 L Niskin bottle during summer and with a Rosette sampler system in winter and spring. All seawater samples were directly siphoned from Niskin bottles into calibrated 100 mL borosilicate glass narrow-mouth Winkler bottles using a silicon tube.

For each depth, seven replicates were fixed (biological activity immediately stopped), to provide the initial oxygen concentration. The two other sets of seven replicates, dark and transparent, were filled and incubated for 24 h. The surface communities were incubated on deck for 24 h in a large 2000 liter tank with continuous circulation of surface seawater to maintain the temperature of the surface waters and natural solar radiation. Bottles were covered with neutral screens to reduce incident radiation by 20 %, in addition to the 8 to 12 % reduction in photosynthetically active radiation transmittance by the bottles themselves (Agustí et al., 2014). The light conditions experienced by the incubated communities mimic those in the upper layer of the ocean but represent only an approximation, as the changes in the light environment due to mixing were not reproduced. For intermediate and DCM depths, the dark and transparent bottles were placed inside opaque PVC and transparent polycarbonate incubation cylinders, respectively. Transparent incubation tubes were fitted with a combination of neutral density (LEE 210) and blue (HT061 Mist, 62.4 % transmission) filters to simulate the irradiance levels experienced by the community at their original sampling depth. Incubation tubes were filled with surface seawater and connected to a closed circuit pump incubator with a temperature control, holding the temperature within ± 0.5 °C of the in situ temperature and set according to the temperature profile retrieved from the CTD cast. At the end of the incubation period, light and dark bottles from each depth were fixed to determine final O₂ concentrations.

Planktonic metabolism was evaluated from changes in dissolved oxygen concentrations, which were determined by automated high-precision Winkler titration with a potentiometric end-point Metrohm 808 Titrando (Oudot et al., 1988). CR and NCP were calculated from changes in dissolved oxygen concentrations, before and after incubation of samples under “dark” and “light” conditions, respectively, and GPP was calculated as $\text{NCP} + \text{CR}$. We used 0.01 N (SD ± 0.000141) thiosulfate solution and the reagents recommended by Carrit and Carpenter (1966).

Volumetric metabolic rate estimates (GPP, CR and NCP) for the three different cruises were tested for normality before statistical analysis via Shapiro–Wilk tests with a 0.05 signif-

icance level, and homogeneity of variances was tested using the Levene test. When GPP, CR and NCP estimates deviated from a normal distribution ($p > 0.05$), a Kruskal–Wallis test was used to compare variables. The Kruskal–Wallis test is a non-parametric equivalent to a one-way analysis of variance by ranks. It tests the null hypothesis that three or more groups all come from the same distribution. It uses the ranks of data and is therefore resistant to outliers. Metabolic rates are expressed as $\text{mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$ and specific metabolic rates as $\text{mmol O}_2 \text{ mg Chl } a^{-1} \text{ d}^{-1}$.

Integrated metabolic rates were calculated by adding up the weighted-average rate between consecutive sampling depths, from the surface layer to the DCM (1 % PAR) and standard errors were calculated using error propagation. Because the depth of integration differed, for comparisons we used the depth-averaged rate, calculated as the ratio between the mean integrated rate and the depth of integration.

2.3 Experimental assessment of the temperature dependence of community respiration rates

During the spring, we performed experimental temperature manipulations at each of the 13 sampled stations to test the response of planktonic CR rates to temperature increase. Seawater was sampled from 10 m above the DCM and incubated at different temperatures. At this depth (10 m above DCM) plankton communities receive more light than at the DCM (Teira et al., 2005), but experience almost the same physical and chemical conditions, so production and biomass are expected to be close to the highest values in the water column. The chlorophyll maximum is somewhat deeper than the depth of maximum photosynthetic rate and of the biomass maximum for photosynthetic cells. In the Atlantic Ocean the DCM is generally not a biomass maximum but rather the result of a decrease of the carbon to chlorophyll *a* ratio with depth (Marañón et al., 2000). Seawater was siphoned into calibrated dark 100 mL Winkler bottles and incubated into opaque PVC tubes to protect them from light. Seven initial replicates were used to determine the initial oxygen concentration, and a set of seven replicates each were incubated in different temperature treatments. We mimicked four temperatures of the in situ profiles: (1) in situ temperature at 10 m above DCM depth (81 ± 6 m), (2) a temperature corresponding to the intermediate depth (45 ± 2.5 m), (3) surface (5–6 m) temperature, and (4) 3 °C above surface temperature. The resulting range of the experimental temperatures for incubations varied between 3 and 7 °C across the experiments performed. Experimental bottles were incubated for 24 h as indicated above and the CR rates were determined following the same methodology as outlined above.

Whereas the experimental assessments use the same community, the evaluation of the temperature dependence of metabolic rates across stations is confounded by the changes in community. Indeed, previous examinations of

the temperature dependence of metabolic rates have demonstrated that bulk rates (i.e., $\text{mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$) are dependent on both community biomass and temperature, with the biomass-specific rate being the component that is temperature dependent and conforming to the temperature dependence expected by the Arrhenius law and metabolic theory (e.g., Regaudie-de-Gioux and Duarte, 2012). Metabolic theory states that metabolic rates are a function of biomass and temperature (Brown et al., 2004), whereas biomass is not necessarily temperature dependence, so that use of bulk rates conceals the role of temperature. Moreover, previous research on the temperature dependence of metabolic rates shows that the most effective metric to standardize for community biomass is chlorophyll *a* concentration both for GPP and CR (Regaudie-de-Gioux and Duarte, 2012).

Hence, we standardized the rates per unit chlorophyll *a* to allow for cross-station comparison of temperature-dependent metabolism and comparisons of experimental assessments with previous assessments.

The activation energy (E_a) was derived from the slope of the Arrhenius plot, which shows the relationship of the natural logarithm of Chl *a*-standardized $\text{CR}_{\text{Chl } a}$ and $\text{GPP}_{\text{Chl } a}$ rates ($\text{mmol O}_2 \text{ mg Chl } a^{-1} \text{ d}^{-1}$) with the inverted water temperature ($1/kT$) where k is the Boltzmann's constant ($8.617734 \times 10^{-5} \text{ eV K}^{-1}$) and T is the temperature in Kelvin degrees ($^{\circ}$ K) (Gillooly et al., 2001; Brown et al., 2004).

2.4 Satellite images

Satellite images were retrieved from the AQUA MODIS (or Moderate Resolution Imaging Spectroradiometer) satellite. In order to make a unique map for each cruise, images of chlorophyll *a* and surface water temperature were created using an average of 8 days from the central day station of the cruise (i.e, Leg 1 (winter): central date was 19/02/2011 and the average image was from 18/02/2011 to 25/02/2011). The information was processed with the SeaDAS software and maps were created using ArcGis software by Esri.

3 Results

All three cruises were characterized by a gradient of cooler waters in the eastern basin to warmer waters in the western basin (Figs. 2a and 3b). Seasonal temperature differences were also significant (Kruskal–Wallis test, $p < 0.0001$) with mean temperature (\pm SE) of 22.4 ± 0.13 $^{\circ}$ C during the Northern Hemisphere winter, 19.5 ± 0.6 $^{\circ}$ C during spring (where stations were at generally higher latitudes) and warmer temperatures (24.4 ± 0.4 $^{\circ}$ C) during summer. The seawater temperature also declined by about 1.7 $^{\circ}$ C (winter), 1.1 $^{\circ}$ C (spring), and 3.7 $^{\circ}$ C (summer) from the surface to the DCM depth (Table 1, Fig. 2a). The deep chlorophyll maximum depth (Z_{DCM}), varied greatly from a minimum of 20 m in spring to a maximum of 165 m in winter, with a mean value of 114 ± 4 m for all stations (Table 2, Fig. 2b).

Chlorophyll *a* concentrations showed temporal and spatial variations. The mean (\pm SE) chlorophyll *a* concentration was similar in winter and summer (0.20 ± 0.01 and $0.21 \pm 0.02 \text{ mg Chl } a \text{ m}^{-3}$, respectively), but higher concentrations were measured during spring ($0.30 \pm 0.07 \text{ mg Chl } a \text{ m}^{-3}$). This difference is due to the maximum value of chlorophyll *a* measured at the eastern basin in surface waters ($1.63 \text{ mg Chl } a \text{ m}^{-3}$, Table 1, Fig. 2b). The satellite imagery revealed a region of high chlorophyll *a* concentrations in the eastern basin, affected by the northwest African upwelling (Fig. 3a). Most of the stations were occupied within the highly oligotrophic waters of the subtropical gyre, except for the northern stations in the eastern basin during spring, which extended to more productive waters (Figs. 2b and 3a). Chlorophyll *a* concentrations decreased significantly with seawater temperature ($R^2 = 0.19$, $p < 0.0001$, $N = 194$) and increased with depth from surface waters to DCM depths in winter and summer. In spring, higher chlorophyll *a* concentrations were found in surface and 20 % PAR depths than at the DCM (Table 1, Fig. 2b), which indicates a fluorescence instead of a chlorophyll maximum.

Sea surface salinity showed significant differences (Kruskal–Wallis test, $p < 0.0001$), between seasons, with lower values during spring (mean \pm SE; 36.5 ± 0.06) and

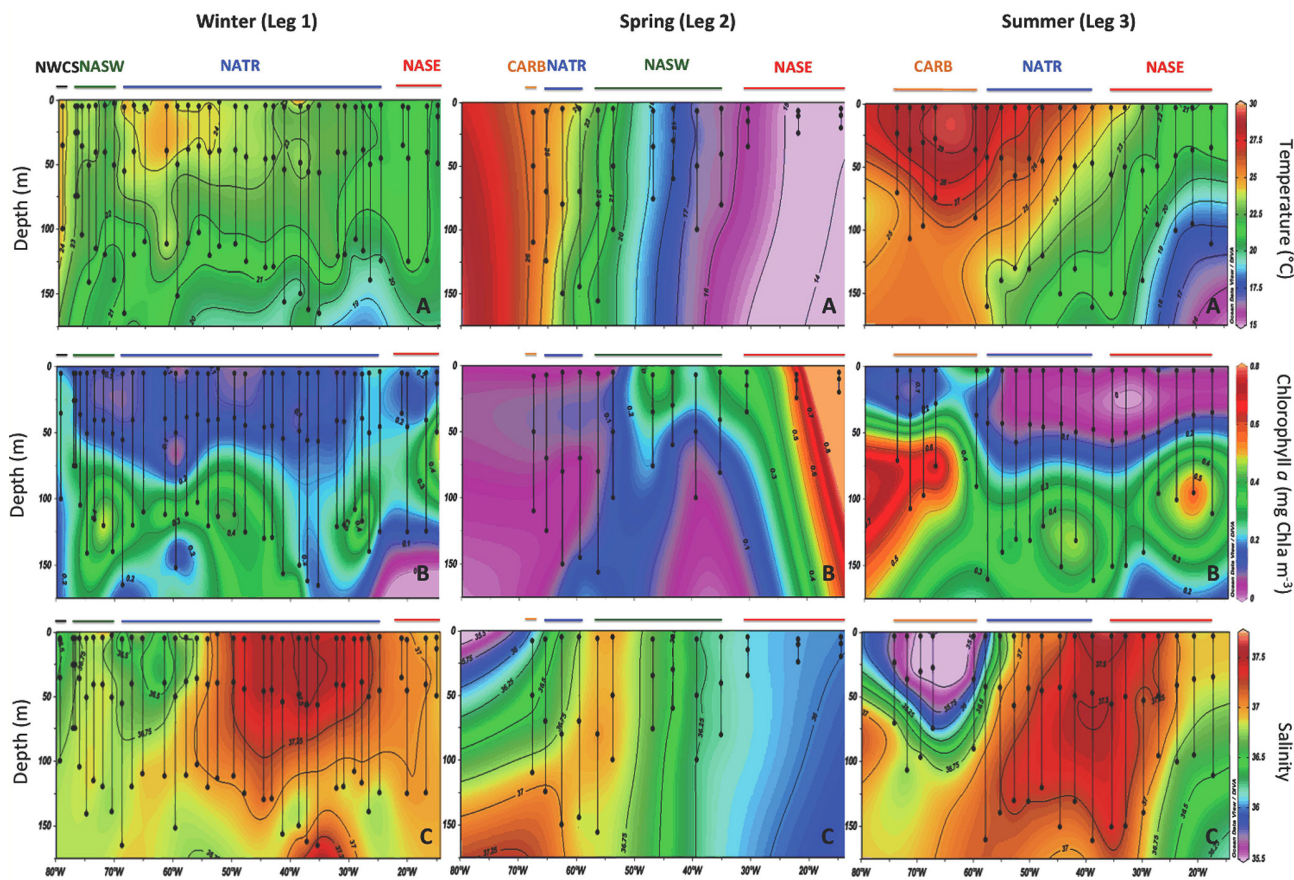

Figure 2. Contour plots for (a) temperature ($^{\circ}\text{C}$), (b) chlorophyll a ($\text{mg Chl } a \text{ m}^{-3}$) and (c) salinity of the profiles sampled (black lines) in Leg 1–winter, Leg 2–spring and Leg 3–summer. Black points indicated the three sampled depths (surface, 20 % PAR and DCM) in each station.

higher values during summer (36.8 ± 0.08) and winter (37 ± 0.03). The lowest value was found at the Caribbean Province (35.9 ± 0.13), probably due to equatorial water that carries a summer seasonal Amazon signal (Dessier and Donguy, 1994), while the high evaporation and lack of riverine inputs close to the NATR Province resulted in higher salinity (37 ± 0.03) for the open ocean region (Fig. 2c).

The overall mean ($\pm\text{SE}$) of volumetric CR rate for the study area was $1.70 \pm 0.23 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$. CR rates showed a minimum during winter and summer in deep and cold waters ($0.01 \pm 0.27 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$ at 103 m, 21.5°C and $0.01 \pm 0.15 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$ at 100 m, 18°C , respectively) and a maximum during summer in the Caribbean shallower and warmer waters ($28.42 \pm 0.11 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$ at 23.5 m, 28°C). Mean volumetric CR rates were lower during winter at the three sampled depths, and higher rates were observed during spring and summer cruises (Fig. 6a).

The overall mean ($\pm\text{SE}$) volumetric GPP rate for the study area was $1.42 \pm 0.16 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$. GPP followed similar patterns as CR, varying from below detection limit during the winter and summer cruises in surface waters to a maximum value of $18.01 \pm 0.11 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$ in the

warmest Caribbean waters during summer. The highest mean GPP rates were measured during spring at the three sampled depths (Fig. 6b).

The overall mean ($\pm\text{SE}$) NCP rate was positive, indicative of autotrophic planktonic metabolism across seasons ($0.19 \pm 0.24 \text{ mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$). NCP did not differ significantly among cruises (Kruskal–Wallis test, $p > 0.05$), whereas CR and GPP were significantly higher for the spring cruise (Kruskal–Wallis test, $p < 0.0001$). NCP did, however, show contrasting vertical patterns in each season. The communities sampled during winter were net autotrophic ($\text{NCP} > 0$) from surface to DCM. During spring, autotrophic communities prevailed in the surface and 20 % PAR layers and heterotrophic communities dominated at the deepest depths, while summer showed the reverse pattern (Fig. 6c).

The mean integrated GPP rate in spring was 3.8-fold higher than in summer and 2-fold higher than in winter. The minimum measured value was observed in winter, while the maximum was measured during the spring cruise. This pattern was also observed for CR mean integrated rates. The highest mean integrated CR rate was found in spring and

Figure 3. Satellite images showing 8-day-average chlorophyll *a* (a) and surface water temperature (b) from the date of the central station sampled in winter, spring and summer cruise.

lower and similar mean integrated CR rates were observed in winter and summer (Table 2).

Integrated NCP rates varied greatly from net autotrophic (NCP > 0) to net heterotrophic (NCP < 0) across stations and seasons. However, the medians of integrated NCP showed a prevalence of autotrophic communities for winter, spring and summer cruises (Table 2). The mean (\pm SE) integrated GPP / CR ratio confirmed an overall net autotrophic metabolism, with an overall mean of 1.39 ± 0.27 and no significant difference between cruises (Kruskal–Wallis test, $p > 0.05$). However, it is observed that the mean integrated GPP / CR ratio decreased from winter to summer (Table 2). Using integrated rates, autotrophic communities (NCP > 0) represented about two-thirds of the total sampled stations (68.6, 61.5 and 65 % for winter, spring and summer, respectively).

Net autotrophic communities were dominant across the 5 different Longhurst biogeochemical provinces (Longhurst, 1998, 2007) occupied during the three cruises (Table 3). Mean NCP and CR rates showed no significant differences between provinces (Kruskal–Wallis test, $p > 0.05$), with the NASE province being the most autotrophic region and the

NASW region the most heterotrophic. However, mean GPP showed significant differences across provinces (Kruskal–Wallis test, $p < 0.05$), decreasing from the most productive regions NASE and CARB to NASW, NWCS and NATR, with the latter being the least productive region. The mean GPP / CR ratio, however, showed no significant differences between provinces and all showed medians around 1 (Table 3).

CR_{Chl a} and GPP_{Chl a} rates, binned by 1 °C, increased with increasing seawater temperature during the spring cruise ($R^2 = 0.50$, $p = 0.01$; $R^2 = 0.60$, $p = 0.005$, respectively). During winter, CR_{Chl a} showed a significant temperature dependence (linear regression, $R^2 = 0.62$, $p = 0.036$) but not GPP_{Chl a} ($R^2 = 0.32$, $p > 0.05$). Finally, in summer, GPP_{Chl a} increased with temperature ($R^2 = 0.36$, $p = 0.05$) but there was no significant relation for CR_{Chl a} ($R^2 = 0.13$, $p > 0.05$) (Fig. 4a, b). The activation energies (E_a) for CR_{Chl a} were higher than those for GPP_{Chl a} in winter and spring, but not in summer (Table 4). The experimental temperature manipulations showed a significant increase of CR_{Chl a} with increasing temperature ($R^2 = 0.65$, $p = 0.0009$). The E_a derived from the experiments of temperature

dependence of $\text{CR}_{\text{Chl } a}$ ($1.64 \pm 0.36 \text{ eV}$) was not significantly different from those derived from in situ data (Table 4, Fig. 5), demonstrating consistency between experimental and in situ relationships. Indeed, use of the Arrhenius linear relationship derived experimentally from temperature manipulations to predict the in situ values yields predicted values consistent with the observed ones, with the slope of the relationship between observed and predicted $\text{CR}_{\text{Chl } a}$ not differing significantly from 1 (linear regression model II equation, slope (\pm SE) = 1.32 ± 0.23).

4 Discussion

Plankton metabolism showed considerable variation along the longitudinal sections examined in this study of the subtropical North Atlantic Ocean. Plankton metabolism had been poorly studied in the western basin of the North Atlantic Ocean, as almost all rates reported for the northern subtropical Atlantic are derived from the eastern basin (Reguadie-de-Gioux and Duarte 2012), except a few studies derived from the Bermuda Atlantic Time-series Study (BATS) in the Sargasso Sea (Williams et al., 2013). Indeed, the western and eastern basins, separated by the Mid-Atlantic Ridge, differ significantly in key physical, chemical and biological properties, such as water temperature, chlorophyll *a* concentrations and salinity (Sathyendranath et al., 1995; Li and Harrison, 2001). Our results show a longitudinal eastward decreasing temperature gradient from warmer superficial waters in the western basin to a cooler eastern basin, with colder areas supporting higher chlorophyll *a* concentrations. The lowest chlorophyll *a* concentrations were found in the oligotrophic subtropical North Atlantic Gyre region, and the highest rates corresponded to waters of the northwest African upwelling (González et al., 2002). The chlorophyll *a* concentration values were on average ($0.22 \pm 0.02 \text{ mg Chl } a \text{ m}^{-3}$) within the ranges previously reported for the North and South Atlantic subtropical gyres (González et al., 2002; Teira et al., 2005).

Here we report a high temporal and spatial variability of metabolic rates in the subtropical North Atlantic Ocean. Such variability can be due to atmospheric forcing (i.e., North

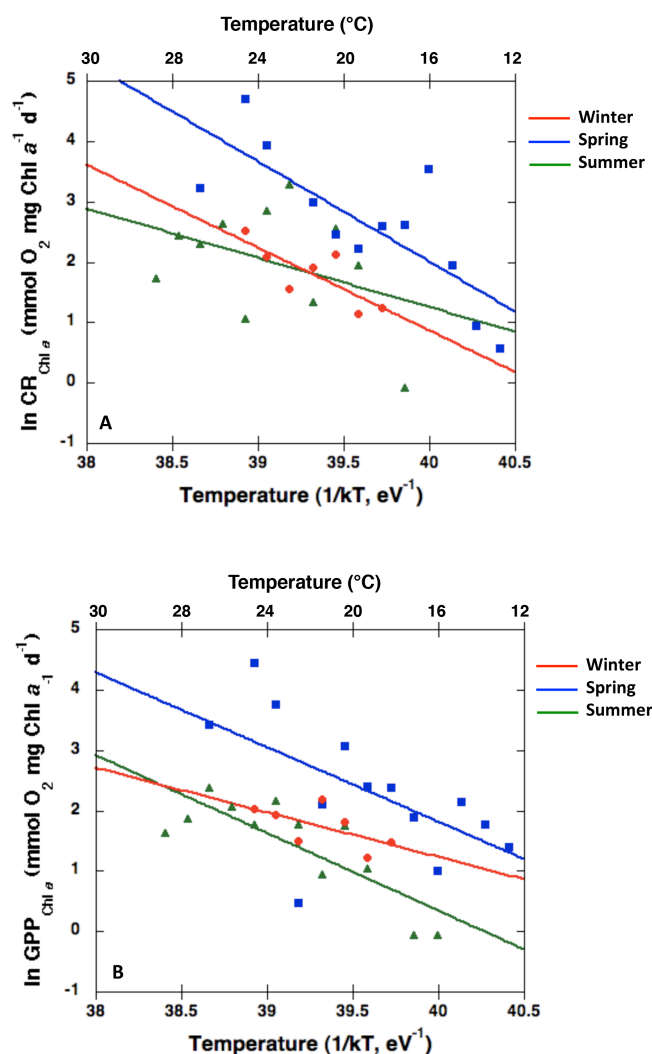

Figure 4. Arrhenius plots showing the relationship between Chl *a*-specific average rates (a) $\text{CR}_{\text{Chl } a}$ and (b) $\text{GPP}_{\text{Chl } a}$ within 1°C bins and the inverted water temperature ($1/kT$, where k is the Boltzmann's constant, $8.617 \times 10^{-5} \text{ eV } \text{K}^{-1}$, and T is the water temperature in $^\circ\text{K}$) for legs 1, 2 and 3.

Figure 5. Arrhenius plot showing the relationship between average Chl *a*-specific respiration rate within 1 °C bins and the inverted water temperature ($1/kT$, where k is the Boltzmann's constant, $8.617 \times 10^{-5} \text{ eV k}^{-1}$, and T is the water temperature in °K) for experimental temperature manipulations conducted during the spring cruise as well as Arrhenius plots for winter, spring and summer cruises for comparison.

Atlantic Oscillation), as interannual variability in $p\text{CO}_2$ correlated with temperature and mixed-layer depth anomalies, can affect the nutrient supply to the euphotic zone (Gruber et al., 2002). Physical forcing mechanisms such as mesoscale instabilities can act as important sources of organic carbon (González et al., 2001) and nutrients (Garçon et al., 2001) to the pelagic ecosystems in oligotrophic areas. Also, intrinsic factors, such as changes in phytoplankton community structure and trophic dynamics (Serret et al., 2009) can influence the variability of plankton community metabolic rates. High temporal and spatial variability of metabolic rates between stations and cruises has been observed in the subtropical North Atlantic Ocean, with higher GPP and CR rates in spring (González et al., 2002) and in the eastern basin, and lower metabolic rates in winter and summer and in the western basin. During the spring season in the mid-latitude North Atlantic Ocean, the westerly winds decrease and the solar radiation increase, supporting the conditions for a phytoplankton bloom (Harrison et al., 2001). Depletion of nutrients with higher stratification of the water column in summer leads to a decrease in productivity and metabolic rates (González et al., 2001), with a secondary bloom developing with the onset of mixing during fall and a subsequent decrease of photosynthetic rates with the reduction of solar radiation during winter (Longhurst, 1998).

The subtropical North Atlantic Ocean showed a net metabolic balance in this study, with a prevalence of autotrophy in 66% of the communities. The prevalence of autotrophic conditions in the three cruises conducted is in contrast to previous reports of a prevalence of heterotrophy in oligotrophic gyres (del Giorgio et al., 1997;

Figure 6. Mean \pm SE for (a) community respiration (CR), (b) gross primary production (GPP) and (c) net community production (NCP) ($\text{mmol O}_2 \text{ m}^{-3} \text{ d}^{-1}$) for each season (winter, spring and summer) at the three sampled depths (surface, 20 % PAR and DCM).

Duarte and Agustí, 1998; Duarte et al., 2013) and for the subtropical North Atlantic Ocean (Duarte et al., 2001; González et al., 2002; Serret et al., 2002, 2006; Morán et al., 2004; Aranguren-Gassis et al., 2011). However, some studies have also shown balanced metabolism (Williams, 1998;

Aranguren-Gassis and Serret, 2012) or a prevalence of autotrophic communities (Kähler et al., 2010), leading to challenges in the view that oligotrophic regions of the ocean support heterotrophic plankton communities (Williams et al., 2013). These contrasting results may be due to interannual variability in ocean metabolism, which has not been assessed as of yet, but has been shown to be important in driving variability in satellite-based primary production estimates (Behrenfeld and Falkowski, 1997) and in the inorganic carbon cycle (Gruber et al., 2002). Alternatively, previous assessments were all based on the eastern basin of the subtropical North Atlantic Ocean, which suggests possible differences across basins. The eastern basin of the North Atlantic receives allochthonous organic carbon inputs, both as production exported from the North African upwelling (Pelegri et al., 2005) and atmospheric inputs (Dachs et al., 2005), which must, therefore, support balanced or autotrophic metabolism. Sources of allochthonous organic carbon and nutrients into the western basin are less evident, but mainly come from large rivers such as the Amazon and Orinoco that discharge $70\,140\text{ km}^3\text{ yr}^{-1}$ of freshwater into the Atlantic western basin (Franzinelli and Potter, 1983; Lewis et al., 1990). An autotrophic status suggests either enhanced GPP or reduced inputs of allochthonous organic carbon (reduce CR), both contributing to positive NCP.

The metabolic theory of ecology (MTE, Gillooly et al., 2001; Brown et al., 2004) predicts an increase in the metabolic rates with increasing temperature, confirmed for plankton communities (López-Urrutia et al., 2006; Regaudie-de-Gioux and Duarte, 2012). Our results confirm these expectations and show a clear temperature dependence of standardized chlorophyll *a* metabolic rates (GPP and CR) along the temperature range measured (14 to 29 °C). Metabolic responses to temperature are dependent on the availability of other resources, such as light, nutrients or organic matter, to support autotrophic or heterotrophic metabolism (López-Urrutia and Morán, 2007). Our results show that about 50 % of the variability in respiration rates among plankton communities in the subtropical Atlantic Ocean can be accounted for by temperature differences, confirmed by the results of our experimental temperature manipulations. This suggests that whereas other resources may contribute to explain the 50 % of the variability in respiration rates that cannot be accounted for by temperature differences, the availability of resources is still sufficient to leave scope for metabolic control by temperature. The activation energy values for GPP and CR were 2 to 4.5-fold higher than those reported by Regaudie-de-Gioux and Duarte, 2012 ($E_{\text{aGPP}} = 0.32\text{ eV}$ and $E_{\text{aCR}} = 0.66\text{ eV}$), measured across a much wider temperature range (0 to 29 °C) across the ocean. The empirical activation energies for CR reported in this study showed consistently higher values than those derived for Atlantic communities by López-Urrutia et al. (2006) ($E_{\text{aCR}} = 0.65\text{ eV}$) and Regaudie-de-Gioux and Duarte (2012) ($E_{\text{aCR}} = 0.92\text{ eV}$), those inferred from ETS activity (Arístegui and Montero,

1995; $E_{\text{aCR}} = 0.7044\text{ eV}$), and those observed for respiration rates in aquatic ecosystems in general (Yvon-Durocher et al., 2012; $E_{\text{aCR}} = 0.65\text{ eV}$). The results presented here also confirm a general higher activation energy for CR than GPP in the subtropical North Atlantic Ocean, consistent with expectations from metabolic theory (Brown et al., 2004; Harris et al., 2006; López-Urrutia et al., 2006) and previous global analyses (Regaudie-de-Gioux and Duarte, 2012). However, the experimental E_{aCR} , at $1.64 \pm 0.36\text{ eV}$, was higher, although not significantly so, than the average ($1.45 \pm 0.6\text{ eV}$) determined through comparative analyses across communities, suggested that the temperature dependence of plankton communities exposed to short-term temperature increase overestimates that of communities pre-adapted to different temperature regimes. Most importantly, our results show a remarkable consistency between activation energies for respiration rates derived from the comparative analysis of in situ rates, and those derived from experimental manipulation of temperature. Hence, the temperature dependence of planktonic metabolism reported here helps to explain spatial and seasonal patterns in planktonic metabolism in the open ocean. The North Atlantic Ocean constitutes the largest ocean sink for atmospheric CO₂ in the Northern Hemisphere (Gruber et al., 2002), storing 23 % of the global oceanic anthropogenic CO₂, despite covering only 15 % of the global ocean area (Sabine et al., 2004). Long-term trends indicate that the subtropical gyre of the North Atlantic Ocean is, at present, acting as a significant sink for anthropogenic CO₂ (Bates et al., 2002). However, the results presented here show that the metabolic balance of the subtropical North Atlantic Ocean may be highly sensitive to warming. Assuming the forecasted ocean warming of 1–3 °C by the end of the century (IPCC, 2007), our finding of an increase in respiration rates with warming suggests that the role of plankton communities in the subtropical North Atlantic communities as significant CO₂ sinks may be weakened substantially or even revert to becoming CO₂ sources to the atmosphere in the future. This consistency confirms the predictive power of the metabolic theory of ecology to predict the responses of plankton community metabolism to foretell negative feedbacks of warming on the CO₂ sink capacity of marine biota (López-Urrutia et al., 2006), possibly shifting communities (Lomas and Bates, 2004) toward a higher prevalence of heterotrophy across the subtropical North Atlantic.

Acknowledgements. This is a contribution to the Malaspina Expedition 2010, funded by the INGENIO 2010 CONSOLIDER program (ref. CDS2008-00077) of the Spanish Ministry of Economy and Competitiveness. We thank the captains and crews of R/V *Sarmiento de Gamboa* and R/V *Hespérides* and the UTM for their help onboard and technical support, M. Fuster for help with mapping and satellite imagery, and the participants of the Malaspina Expedition and Buque Escuela projects for providing CTD data and general support. L. S. García-Corral was supported by a JAE Pre-doc fellowship from the Spanish National Research Council (CSIC) and the BBVA Foundation, Spain.
