Abstract :

While more and more investigations are done to study hyperthermophilic exoelectrogenic communities from environments, none have been performed yet on deep-sea hydrothermal vent. Samples of black smoker chimney from Rainbow site on the Atlantic mid-oceanic ridge have been harvested for enriching exoelectrogens in microbial electrolysis cells under hyperthermophilic (80 °C) condition. Two enrichments were performed in a BioElectrochemical System specially designed: one from direct inoculation of crushed chimney and the other one from inoculation of a pre-cultivation on iron (III) oxide. In both experiments, a current production was observed from 2.4 A/m² to 5.8 A/m² with a set anode potential of -0.110 V vs Ag/AgCl. Taxonomic affiliation of the exoelectrogen communities obtained on the electrode exhibited a specific enrichment of *Archaea* belonging to *Thermococcales* and *Archeoglobales* orders, even when both inocula were dominated by Bacteria.

Highlights

► Development of a new semi-automatic hyperthermophilic bioelectrochemical system. ► Enrichment of hyperthermophilic exoelectrogen community in MEC system. ► Specific enrichment of *Archaea* in MEC system. ► Potential exoelectrogenic capability of *Thermococcus* spp.

Keywords : Hyperthermophilic exoelectrogens, Deep-sea hydrothermal vent, Microbial electrolysis cell, External Electron Transfer

1. Introduction

Since the discovery of the first deep-sea hydrothermal vent in 1977, many studies have expanded our understanding of extremophilic life forms in those environments. Considered as primordial environments similar to the early Earth conditions (Martin et al., 2008; Takai et al., 2006), the deep-sea hydrothermal ecosystems are regarded as a good model to study the origins and evolution of life on Earth (Takai et al., 2006). In addition, in recent years many authors have focused on the great potential of extremophilic marine microbes for their use as prolific producers of bioactive substances (enzymes, metabolic products...) (Poli et al., 2017).

The "black smoker" deep-sea hydrothermal vents, located along the ridges of the Atlantic, Pacific and Indian oceans, are the result of volcanic activities that generate hydrothermal chimneys composed of polymetallic sulfide minerals (heterogeneous pyrite) (Dick et al. 2013). Those environments exhibit dynamic habitats that are characterized by large steep thermal and chemical gradients. These gradients provide a wide range of growth conditions for many extremophilic microorganisms growing as biofilms and being the base of these specific deep-sea ecosystems (Flores et al. 2011; Kristall et al. 2006). Thermophilic microorganisms from the Archaea domain, mainly belonging to the orders *Thermococcales*, *Methanococcales*, and *Archaeoglobales* have been identified in these environments, as well as mesophilic and thermophilic microorganisms from the *Bacteria* domain belong to *Epsilon-proteobacteria* (Huber et al. 2010; Vetriani et al. 2014) and to the orders *Aquificales* and *Thermotogales* (Miroshnichenko and Bonch-Osmolovskaya, 2006).

Considering the mineralogical composition of these hydrothermal chimneys (polymetallic massive sulfide), it appears likely that a significant proportion of its microbial populations is dependent on energetic metabolisms based on the dissimilatory reduction of insoluble "metals" or sulfur compounds (Cao et al. 2014; Kohn et al. 2015).

As the microbial cell envelope is neither physically permeable to insoluble minerals nor electrically conductive, microorganisms have evolved strategically to exchange electrons with insoluble extracellular minerals, a mechanism known as the extracellular electrons transfer (EET) (Hinks et al. 2017; Shi et al. 2016). The first described EET capable bacteria were *Shewanella* and *Geobacter* (Shi et al. 2007). The role of membrane bound electron transport chains in carrying out EET was well acknowledged, but the exact mechanisms are still not completely understood (Kumar et al. 2017). Most of the knowledge about EET in microbes is derived from studies in bioelectrochemical systems (Allen and Bennetto, 1993; Logan et al. 2006; Schröder et al. 2015) which helped to define a novel group of microorganisms called exoelectrogens. These exoelectrogenic microorganisms are capable of extracellular electron transfer to a solid electrode, which are used in Microbial Electrochemical Technologies (METs) such as Microbial Fuel Cells (MFC) and microbial electrolysis cells (MEC) (Doyle and Marsili, 2015). In the past years, exoelectrogenic activity has been reported in almost 100 microbial species which are mostly affiliated with the bacterial phylum *Proteobacteria* (Koch and Harnisch, 2016). All these microorganisms are mesophilic and grow optimally at moderate temperatures, ranging from 20 °C to 45 °C.

To date, only four thermophiles isolated from extreme natural environments, *Thermincola ferriacetica* (Marshall and May, 2009), *Thermincola potens* strain JR (Wrighton et al. 2011), *Calditerrivibrio nitroreducens* (Fu et al. 2013) and *Thermoanaerobacter pseudethanolicus* (Lusk et al. 2015), were shown to generate electricity in MFCs operating at a temperature higher than 50°C. Moreover, it is only very recently that three hyperthermophilic strains, *Pyrococcus furiosus*, *Geoglobus ahangari* and *Ferroglobus placidus* have been shown to have the capacity to produce electricity in MFC or MEC (Sekar et al. 2017; Yilmazel et al. 2018). This would be the three first hyperthermophilic archaeon strains described having the capacity of EET. Several studies reported the enrichment of mixed cultures of efficient thermophilic exoelectrogens on the anode of METs (Ha et al., 2012; Mathis et al., 2007; Wrighton et al., 2008). More recently, two exoelectrogenic biofilms have been enriched at 70 °C from a high-temperature petroleum reservoir (Fu et al. 2015) and at 80 °C from Red Sea brine pools (Shehab et al. 2017) on the anode of MFC systems.

To the best of our knowledge, no exoelectrogenic biodiversity enrichment from deep-sea hydrothermal vents has been achieved yet, while it seems likely that some microbial populations require this type of energy metabolism to expand in these particular environments. Interestingly, a MFC was installed at a hydrothermal vent field (Girguis and Holden, 2012) showing for the first time, the *in situ* electricity generation in those extreme ecosystems. More recently it has been demonstrated that there is a widespread and distant electron transfer through the electrically conductive hydrothermal chimney by the internal oxidation of the hydrothermal fluid coupled to the reduction of oxygenated seawater at the external side of the chimney (Yamamoto et al. 2017). This electricity generation in deep-sea hydrothermal systems must affect the surrounding biogeochemical processes and the development of microbial communities through potential EET-capable microorganisms.

The aim of this study was to promote and identify a part of the exoelectrogenic microbial community from a hydrothermal chimney of the Rainbow site on the Atlantic mid-oceanic ridge. For this investigation, two experiments were carried out using a semiautomatic two-chamber BioElectrochemical System Stirred-Reactor (BES) prototype (graphical abstract), operating at high temperatures (80 °C). The first one was performed to enrich microbes after direct inoculation of the BES with a chimney fragment. The second enrichment in BES was carried out from an inoculum obtained by a microbial enrichment culture in flask on Fe (III) oxide particles as electron acceptor using the same hydrothermal sample. This was done in order to pre-cultivate potential exoelectrogenic microbes on iron oxide and observing the impact on biodiversity obtained subsequently in BES. The evolution of current production, of microbial diversity and biomass during the different enrichments were studied through electrochemical method and molecular biology survey.

2. Material and methods

2.1. Sample collection and preparation

The inoculum used for all the experiments was collected on the Rainbow hydrothermal vent field (36°14'N, MAR) by the Remote Operated Vehicle VICTOR 6000 during EXOMAR cruise in 2005 led by IFREMER (France) on board RV L'Atalante (Godfroy, 2005). Sample (EXO8E1) was collected from the breaking off of a piece of a high temperature active black smoker using the arm of the submersible and bring back to the surface into a decontaminated insulated box. On board, chimney fragments were anaerobically crushed into an anaerobic chamber (La Calhene, France) and stored into flasks under anaerobic conditions (anoxic seawater at pH 7 with 0.5 mg/L of Na₂S and N₂:H₂:CO₂ (90:5:5) gas atmosphere) and kept at 4 °C. Prior to the experiment, pieces of hydrothermal chimney were removed from the sulfidic seawater flask, crushed in a sterile mortar and pestle in an anaerobic chamber (Coy Laboratories Inc.) and distributed in anaerobic tubes for use in various experiments.

2.2. *Enrichment on iron oxide in flask*

To obtain enrichment of electro-active microbes on insoluble Fe (III) oxide as electron acceptor, 2.5 g of crushed hydrothermal chimney was inserted in 500 mL flask with butyl rubber stopper under nitrogen gas atmosphere filled with 250 mL of anaerobic mineral medium at pH 7 containing 30 g/L NaCl, 0.65 g/L KCl, 0.5 g/L NH₄Cl, 0.3 g/L KH₂PO₄, 0.3 g/L K₂HPO₄, 0.1 g/L MgCl₂, 0.1 g/L CaCl₂, 0.35 g/L Cysteine HCl, 0.2 g/L of yeast extract and 10 mL/l of Balch trace mineral solution (Uzarraga et al, 2011). The media was supplemented with 10 g/L of Fe (III) oxide, 10 mM of acetate and 4 g/L of yeast extract as electron donor and carbon source. The flasks were incubated at 80 °C in static condition until a dark coloration of iron oxide was observed. Two subcultures were performed in the same condition with 1% of inoculum from the previous culture.

2.3. *Semi-Automated Bioelectrochemical Systems*

A prototype of semi-automated BioElectrochemical System in Stirred-Reactor (BES) has been developed to assess the enrichment of hyperthermophilic electroactive microorganisms. The system was composed of a two-chamber jacketed glass reactor (Verre Labo Mula, France) with a 1.5 L working volume, thermostated with a Heating Circulator (Julabo SE 6, France) at 80 °C ± 1 °C,

and separated by an Anion Exchange membrane (Membrane International Inc.). The working electrode was a 20 cm² carbon cloth (PaxiTech SAS, France) with a 3 M Ag/AgCl reference electrode and the counter electrode a 20cm² carbon cloth coated with platinum (Hogarth, 1995).

The bioelectrochemical system was connected to a semi-automated platform previously described (Boileau et al. 2016) to control the composition and rate of gas input (H₂, CO₂, O₂, N₂) with mass flowmeters (Bronkhorst, Netherlands). A continuous monitoring of output gas composition (H₂, N₂, CH₄, O₂, CO₂) were performed using a micro-GC equipped with a catharometric detector (MS5A, SRA Instrument, France) and a CARBOCAP CO₂ probe (Vaisala GMT 221, Finland). To ensure anaerobic condition, the culture medium was continually sparged with a 50 mL/min flow of N₂. The pH was maintained at 7 ± 0.1 by the addition of sodium hydroxide (NaOH 0.5 mM) or hydrochloric acid (HCl 0.5 mM). The stirring, driven by two axial impellers, was set to 150 rpm. All the parameters, as pH and ORP (Mettler Toledo InPro 3253, Switzerland), temperature (Prosensor pt 100, France), stirring speed, gaseous H₂, N₂, CH₄, O₂ and CO₂ concentration and NaOH and HCl consumption, were measured and managed by the BatchPro software (Decobecq Automatismes, France). SP-240 potentiostats and EC-Lab software (BioLogic, France) were used to poise the electrodes at a fixed potential and measure current. All the measured currents are expressed in ampere per square meter of electrode area.

2.4. Operating conditions in BES

Before each experiment, the BES was dismantled, washed, and sterilized by autoclaving at 120 °C for 20 min. Then, the system was connected to the platform and 1.5 L of mineral medium was injected and supplemented with 10 mM acetate and 0.15 g/L of Yeast Extract (YE). The liquid media was set in the operational condition for a few hours prior to perform a cyclic voltammetry (CV, 20 mV/s). First, the system (BES1) was inoculated with 15 g of crushed hydrothermal chimney in anaerobic condition. A chronoamperometry was carried out by the potentiostat to poise the electrode at -0.110 V vs Ag/AgCl (+0.05 vs Standard Hydrogen Electrode), and a measurement of the current was taken every 10 s. A cyclic voltammetry was also performed at the end of the

experiment. Secondly, a new system (BES2) was inoculated in the same condition with 1% of the last enrichments in flask on Fe (III) oxide on yeast extract. An abiotic control and an inoculated but non-polarized control have been performed in the same conditions to exhibit the exoelectrogenic specificity of the biofilm on the polarized electrode.

2.5. Taxonomic and phylogenetic classification

Taxonomic affiliation was performed according to (Zhang et al. 2016). DNA were extracted from 1g of the crushed chimney and at the end of each experiment (BES-1 at 14 days and BES-2 at 11 days): on the scrapings from half of the 20 cm² of working electrode and from 50 mL of the liquid media of the BES and flask enrichments, which were centrifuged and suspended in 1 mL of sterile water. The DNA extraction was carried out using the MoBio PowerSoil DNA isolation kit (Carlsbad, CA USA). The V4 region of the 16S rRNA gene was amplified using the universal primers 515F (5'-GTG CCA GCM GCC GCG GTA A-3') and 806R (5'-GGA CTA CNN GGG TAT CTA AT-3') (Bates et al., 2011) with Taq&Load MasterMix (Promega) and PCR reactions were carried out using C1000 Thermal Cycler (BioRad) with the following conditions: initial denaturation at 94 °C for 3 min followed by 30 cycles of denaturation at 94 °C for 30 s, primers annealing at 50 °C for 30 s and extension at 72 °C for 90 s, followed by a final extension step of 5 min at 72 °C. The amplified gene regions were sequenced on Illumina MiSeq 2500 platform (GeT-PlaGe, France) to generate paired-end 150 bp reads. The reads were merged using the FLASH software. The taxonomic affiliation was performed with the QIIME software package v 1.9.1. Chimeras were removed from the merged sequenced using UCHIME Algorithm. Then, the filtered sequences were clustered into OTUs using the RDP method with a minimum bootstrap confidence of 0.8 and OTUs were affiliated using the Silva database as reference. To analyze the alpha diversity, the OTU tables were rarified to a sampling depth of 10770 sequences per library and two metrics were calculated: the richness component represented by the number of OTUs observed, and the Pielou's index representing the evenness component of our biodiversity. The raw data of barcoding analysis were deposited in the European Nucleotide Archive with the accession number

PRJEB24019. The construction of clone library was performed by amplifying the 16S rRNA genes by previously described PCR method with a FD1 (5'-AGAGTTTGATCCTGGCTCAG-3') and R6 (5'-TACGGCTACCTTGTTACG-3') primer set (Brosius et al., 1981) using Taq&Load MasterMix (Promega). The amplicons were cloned into the pGEM-T easy vector (Promega) and transformed into *E. coli* JM109 competent cells that were grown overnight in LB agar at 37 °C. Fragment of 16S rRNA gene (~1300 bp) of the clones were sequenced by ABI3730xl (GATC Biotech) sequencers. The nucleotide sequences obtained from clone library were deposited in the GenBank database with the accession numbers MG694212 through MG694233

2.6. *Quantitative PCR of archaeal and bacterial 16S rRNA gene copies*

Bacterial and archaeal quantification was carried out by qPCR with SsoAdvanced™ Sybr Green Supermix on a CFX96 Real-Time System (C1000 Thermal Cycler, Bio-Rad Laboratories, CA, USA) with the primers GML5F (5'-GCC TAC GGG AGG CAG CAG-3') and Univ516 (5'-GTD TTA CCG CGG CKG CTG RCA-3') specific to Bacteria (Michotey et al., 2012) and Arc931F (5'-AGG AAT TGG CGG GGG AGC A-3') and m1100R (5'-BTG GGT CTC GCT CGT TRC C-3') for Archaea (Einen et al., 2008). The PCR program was composed of a 10 s denaturation step at 94 °C, a hybridization step of 10 s at 55 °C (Bacteria) or 62 °C (Archaea) and a 10 s elongation step at 72 °C, with melting curves performed at the end of each reaction to ensure product specificity. A standard curve from 10² to 10¹⁰ 16S rRNA gene copies was obtained by diluting pGEM-T plasmids harboring hyperthermophilic bacterial or archaeal rRNA gene fragment obtained from microbial community of interest. The results were expressed in copies number of 16s rRNA gene per gram of crushed chimney, per milliliter of liquid media or per cm² of surface of electrode.

3. Results and discussion

3.1. *Microbial diversity of hydrothermal chimney from Rainbow site of Atlantic Ocean*

Prior to study specifically the electroactive community putatively present on a chimney of the hydrothermal Rainbow site, an analysis of the total microbial diversity present in our crushed chimney inoculum was done by using the Illumina method. The chimney biodiversity (Fig. 1) was

composed of 160 OTUs representing a high richness of species. As indicated by the Evenness index (0.677), the sequences were distributed relatively equally in the different OTUs. Furthermore, the taxonomic affiliation of the 160 OTUs showed that 66% were assigned to *Bacteria* and 33% to *Archaea* domains. This was consistent with the quantitative Polymerase Chain Reaction (qPCR) assays which showed a dominance of *Bacteria* compared to *Archaea* (6.38 ± 0.05 vs 4.77 ± 0.19 log of 16S rRNA gene copies per gram of chimney, respectively). The difference of ratio obtained can be explained by the overestimation of the bacterial quantification by 16S rRNA gene qPCR, because of the high number of gene copies per cells compared to *Archaea* (generally equal to 1 per cell) (cf. rrnDB, (Stoddard et al. 2015)). Within the bacteria domain, the OTUs were mainly assigned to 5 phyla: *Proteobacteria* (58%), *Firmicutes* (3%), *Aquificae* (1%), *Bacteroidetes* (1%) and *Thermodesulfobacteria* (1%) whereas the archaeal OTUs were only identified as *Euryarchaeota* represented by *Thermococcales* (23%) and *Archaeoglobales* (11%). This taxonomic profile was substantially similar to those previously reported on Rainbow chimneys (Cerqueira et al. 2017; Flores et al. 2011), except for the proportion of methanogens and *Desulfurococcales* found significantly lower in our samples. Despite a recognized stability in the conservation of hyperthermophilic microorganisms at low temperature (Wirth, 2017), our samples have been conserved more than 12 years at 4 °C, this could mostly explain the decrease in Archaea diversity.

3.2. Enrichment of anode-respiring community in BES from crushed chimney

To assess the diversity of hyperthermophilic exoelectrogenic microbes from deep hydrothermal vent on conductive electrode, a fraction of a crushed chimney from the Rainbow site was used to inoculate the BES1. To mimic the hydrothermal vent conditions in the BES, a synthetic seawater medium, containing acetate and yeast extract as carbon and energy sources, was used. Indeed, in hydrothermal vent fluid, acetate can be chemically synthesized through Fischer-Tropsch Type (FTT) reaction from H₂ and CO₂, both produced otherwise during serpentinization reaction (Schrenk et al. 2013). Acetate can also be biologically produced during fermentative metabolisms. It should be noted that acetate is not fermentable in the absence of acetoclastic methanogens and

needs an exogenous electron acceptor to be used as energy source for microorganisms' growth. On the other hand, YE mimicked here the organic compounds produced by autotrophic and heterotrophic communities of hydrothermal chimney available for the fermentative/respiratory growth of microorganisms.

While no notable current was observed during the 10 days of experiment in the control experiments (abiotic and killed inoculum), a raise of current density was observed after 6 days of incubation in the BES1 inoculated with crushed chimney (Fig. 2). The maximum current density reached 5.9 A/m² at 8.7 days and remained stable for few hours. The 3 mM of acetate consumed during this period as attested by HPLC measurements (data not shown) was in good agreement with the current production assuming a maximum faradic efficiency at 95-100%, as previously obtained in literature (Sengodan and Hays, 2012). After this period the current density decrease progressively probably due to the exhaustion of growth factors present in the medium and necessary to the biofilm metabolic activity. Indeed after 10 days of culture, the renewal of the medium led again to a current increase of up to 6 A/m² at maximum current density. Similarly, the current decreased after a few hours but remained stable in absence of medium renewal.

Cyclic voltammeteries (Fig. 3) have been performed after inoculation and at the end of experiment in polarized condition to observe the electrochemical profile of ElectroActive Biofilms (EAB) as catalyst of the bioelectrochemical oxidation of acetate. The anode showed the apparition of an oxidation peak with a midpoint potential at -0.100 V (vs. Ag/AgCl) at the end of the experimentation. No oxidation peak was observed for the spent media with a new sterile electrode, suggesting that EET mechanisms were not involving mediators (data not shown). Moreover, the capacitive current (vertical distance between oxidation and reduction waves) increasing between beginning and end of the culture experiments reports an increase of the electrochemical double layer and suggests the presence of a biofilm on the surface of the electrode. Thus, these results suggest the development of EAB with direct EET using acetate as electron donor.

In contrast to the non-polarized culture conditions, microscopic observations over time have revealed the presence of planktonic microorganisms (in the liquid medium) after 9 days of incubation in the polarized electrode culture condition. In addition, the microbial quantification by qPCR of the enrichment in BES1 shows 7.3 ± 0.18 and 9.23 ± 0.04 log of bacterial and archaeal 16S rRNA gene copies per milliliter of liquid media and 7.28 ± 0.53 and 9.73 ± 0.06 log per square centimeter of electrode, respectively. On the contrary, in the non-polarized control, quantification of 16S rRNA copies was under the 2 log of sensitivity threshold of the method, indicating that no significant growth was observed under these conditions in liquid media or on the non-polarized electrode. Thus, the polarization of the electrode (-0.110 V vs Ag/AgCl), which served as an obligatory electrons acceptor to allow the oxidation of acetate or the weak amount of YE, seems essential also for the planktonic microbial growth.

To identify the microbes present on the electrode (Electrode BES1) and in liquid medium (Liquid BES1), a microbial diversity study through sequencing of the hypervariable V4 region of 16S rRNA gene (Fig. 1) have been performed at the end of the enrichment (day 14). 61 OTUs were obtained on Electrode 1 and 58 OTUs in Liquid Media 1, indicating of a loss of biodiversity from environmental chimney (160 OTUs). The sequences obtained are distributed in the different OTUs with however some OTUs more represented than in environmental sample (evenness at 0.452 on Electrode 1 and 0.331 in Liquid Media 1). This can be explained by our selective conditions of enrichment with high temperature and substrate specificity. Based on average abundance analysis, the microbial diversity of enrichment culture was dominated by *Euryarchaeota* phyla (> 70%), either on electrode or in liquid medium. Interestingly, at the genus level, the dominating archaeal OTUs on electrode were closely related to *Geoglobus* spp. (45.2%) and *Thermococcus* spp. (25.6%) whereas the planktonic microbial diversity in liquid medium is especially dominated by uncultured *Thermococcus* spp. (64.1%) rather than *Geoglobus* spp. (13.3%). The bacterial diversity on the electrode and in liquid media were mainly assigned to *Thermodesulfatator* spp. (15.6% and 18% respectively), while the remaining were distributed between members of *Bacillaceae* and *Micrococcaceae* families. These specific enrichments of *Archaea* compared to *Bacteria*

demonstrate a shift in initial microbial community structure from the crushed chimney, surely driven by the specific BES characteristics (i.e., polarized electrode, hyperthermophilic condition).

Due to the limitation for taxonomic affiliation at species level of the Illumina techniques on 290 bp 16S fragments, we performed 16S rDNA clone libraries on ~1300 bp 16S sequence. It allowed identifying the *Thermococcus* spp. as closely related to *Thermococcus thioeducens*, *T. coalecens*, *T. barossi*, *T. peptonophilus*, *T. celer* (98% similarities with them) and an unidentified *Thermococcus* species (95% similarity with *Thermococcus thioeducens*). However, because of the high levels of similarity between species of the genus *Thermococcus*, the taxonomic affiliation through the coding gene for 16S rRNA is not sufficient to determine the *Thermococcus* species present in enrichments.

However, among the *Geoglobus* spp. the taxonomic affiliation from clone libraries has allowed to identify two species: *Geoglobus ahangari* (99% similarity) and a novel genus or species of the *Archaeoglobaceae* family (MG694212 and MG694224: 95 % of similarity vs *Geoglobus ahangari*). This novel taxon is exclusively found on the electrode surface. Interestingly, this affiliation has been possible only through near full 16S rRNA gene sequence (1300 bp) alignment. Indeed, the hypervariable V4 region of the rRNA gene (~290 bp), used to the study of microbial diversity by Illumina-based analysis, did not allow to phylogenetically differentiate this novel taxon from *Geoglobus ahangari*. Differences are remarkable at level of hypervariable V6 to V8 regions.

The discovery of *Geoglobus* species enrichment on the electrode is remarkable. The two species of *Geoglobus* described so far (*G. ahangari* and *G. acetivorans*) are known to grow autotrophically using H₂ or heterotrophically using a large number of organic compounds with in both cases soluble or insoluble Fe (III) oxide as a final electrons acceptor (Manzella et al. 2013). More recently, it has been shown that *Geoglobus ahangari* was exoelectrogenic by direct contact when placed in one-chamber microbial electrolysis cells at 80 °C. In contrast to our results, the current produced was

particularly weak probably due to its use as an axenic culture, and its lack of enzymatic component to resist to oxidative stress on electrode (Yilmazel et al. 2018).

Phylogenetic analysis of 16S rRNA clone libraries has led to the identification of taxon *Thermodesulfatator atlanticus* among the *Thermodesulfatator spp.* previously identified in high throughput sequencing. This bacterium, also isolated from a Rainbow site chimney, is known to be chemolithoautotrophic, sulfate-reducing obligate bacterium that uses H₂ as electron donor and CO₂ as carbon source. Alternatively, it is able to use methylamine, peptone or yeast extract as carbon sources (Alain et al. 2010). A close related species, *Thermodesulfobacterium commune* has already been identified in EAB on electrode of a MFC (Fu et al. 2015)

3.3. Enrichment of hyperthermophilic microorganisms on crystalline Fe (III) oxide

In parallel of the first BES previously described, flask enrichments with insoluble metallic electron acceptor were done. Crushed chimney was inoculated in anaerobic mineral medium added with 10 g/L of crystalline Fe (III) oxide (α -Fe₂O₃; hematite) as electron acceptor (Wahid and Kamalam, 1993), acetate (10 mM) and yeast extract (4 g/L) as energy and carbon source. After 2 days of static incubation at 80 °C, the hematite was completely reduced to black compounds (magnetic particles) and the head space of the flask contained 32% of CO₂, 0.2% of H₂ and 10% of CH₄. A production of acetate was also observed in the liquid media, reaching 12 mM at the end of the experiment. The next subcultures reached the black coloration in less than 24 hours with similar concentration of each gas in the headspace of the flasks and same profile of metabolites in the liquid media. The presence of a thin biofilm could be observed on the surface of the agglomerated iron oxide. An abiotic control with a mix of acetate, yeast extract, H₂, CH₄ and CO₂ didn't show black coloration of iron oxide after one month of incubation at 80 °C. These results suggest the development of a community of both fermentative organisms, producing acetate, and electroactive microorganisms, able to oxidize organic compounds brought by the YE (peptides, carbohydrates, etc.) and acetate in the culture medium for the reduction of crystalline Fe (III) oxide.

The biodiversity enriched in flask was composed of 29 OTUs, and the sequences were relatively concentrated in dominant OTUs (evenness at 0.292). At the family level, the microbial diversity was dominated by bacterial OTUs related to *Clostridiaceae* (73%), and *Thermodesulfobacteriaceae* (3%). The archaeal OTUs represented only 24% of the biodiversity distributed between *Thermococcaceae* (20.5%), *Methanococcaceae* (3%) identified as *Methanotorris igneus* species and *Archaeoglobaceae* (0.5%). The quantification showed an enrichment of 9 log of bacterial and 7 log of archaeal 16S rRNA gene copies which demonstrated a shift of enrichment toward the preferential bacterial growth in opposition with BES enrichment. Interestingly, the taxonomic affiliation showed that members of the *Clostridiaceae* OTUs were closely related in clone libraries to *Caloranaerobacter ferrireducens* (97% of identity) This later microorganism is known to use crystalline Fe (III) reduction as a minor pathway for electron flow while fermenting sugars or amino acids to a mixture of volatile fatty acids (acetate, butyrate) and hydrogen (Zheng et al. 2015). *Archaeoglobaceae* accounted for only 0.5% of the microbial communities in this enrichment and have been closely related from clone libraries analysis to *Geoglobus ahangari* (99% of identity). As mentioned above, *Geoglobus ahangari* is known to reduce amorphous Fe (III) oxide but these culture conditions with crystalline form do not seem to favor its growth (Wahid & Kamalan, 1993). All these results could suggest the organization of a kind of trophic chain in our flask enrichment. The new iron reducing species close to *Caloranaerobacter ferrireducens* would have used organic compounds from yeast extract to reduce crystalline Fe (III) oxide. The *Thermococcus* would have grown on peptides or carbohydrates from yeast extract or partly produced by *Firmicutes*, and both would have produced H₂. The methanogens such as *Methanotorris igneus* would then have used the H₂ to produce methane.

3.4. Solid electron acceptor determine the microbial ecology of electroactive enrichment

In this context, a new BioElectrochemical System (BES2) was inoculated with the flask enrichment on YE/acetate to assess the specificity of the microbial community obtained on the electrode with a different initial microbial composition in the inoculum. Experimental conditions were exactly the

same as for BES1. Contrary to BES1, a lag time of 3 days (Fig. 2) has been observed before the increase of the current. After 4.5 days the current has reached 2.4 A/m² and stayed stable during about 1 day before decreasing rapidly. Phase contrast microscopic observations before the culture medium renewal in BES2 have shown the only presence of irregular coccoid cells. Thereafter, the current density reached a maximum of 3.4 A/m² at 4 days after the renewal of the culture medium. This phase of current production came along with a decrease of acetate as observed in the BES1 (data not shown). Cyclic voltammetry (Fig. 3) exhibited oxidation peak appearing between initial time and final time with a midpoint potential at -0.107 V (vs. Ag/AgCl), slightly offset compared to the one obtained with BES1.

The biodiversity indexes between YE enrichment in flask and BES2 showed a loss of richness of species from 29 to 26 OTUs, and evenness from 0.292 to about 0.17, indicating a loss of biodiversity dominated only by a few OTUs. Furthermore, only *Archaea* were detected in BES2, when they were trivial in Flask enrichment. The dominating OTUs (Fig. 1) were closely related to *Thermococcaceae* uncultured species at 87.2% on electrode and 95.4% in liquid media of total OTUs. The remaining archaeal diversity was composed of *Archaeoglobaceae* spp. (12.7% and 4.5%), with clones affiliated to *Geoglobus ahangari* (99% identity) and unknown species belonging to *Archaeoglobaceae* family (95% identity with *Geoglobus ahangari*) similarly found on BES1 electrode. No *Caloranaerobacter* spp. or *Thermodesulfobacteriaceae* spp. growth was observed on the BES2 neither on electrode nor in liquid media. This is supported by the qPCR, which has shown a drastic difference of 4 log between archaeal (9 log) and bacterial (5 log) 16S rRNA copies per milliliter of liquid media and square meter of electrode.

It should be pointed out that the flask YE enrichment did not promote growth of *Archaeoglobales* or *Archaea* in general, whereas they seemed to be re-enriched in the BES2 conditions. These results suggest the specific enrichment on polarized electrode of *Archaea* belonging to *Thermococcales* and *Archeoglobales* in our BES condition. It is noteworthy that the biodiversity indexes showed a loss of biodiversity in BES compared to crushed chimney due to selective

condition of our experiment to enrich preferentially the electroactive microorganisms. However, in each BES, the richness and the evenness are more important on polarized electrode than in liquid media, suggesting a specific enrichment of more diverse species and better distribution of microbial population on polarized support. According to the absence of growth in non-polarized electrode and the more important diversity on electrode than in liquid, the microbial diversity found in liquid media would arise from EAB which develop on the electrode. This is supported by the really low H₂ production in BES (data not shown) - H₂ being normally produced by *Thermococcus* sp. during fermentative metabolisms - which could be explained by a lack of carbon and energy source in liquid media. Thus, in absence of possible known metabolism for *Thermococcus* species in liquid, we would suggest *Thermococcus* cells to be in quiescent conditions after it is released from EAB. Its growth would thus have an obligatory dependence on the polarized electrode.

If the presence of *Geoglobus* species is consistent with its known capacity to transfer EET with acetate as electron donor (Yilmazel et al. 2018), *Thermococcus* species abundance on polarized electrode is more surprising. *Thermococcales* are known to share an energetic peptidic or carbohydrate metabolisms, associated necessarily or not with the reduction of elemental sulfur (Bertoldo and Antranikian, 2006). In addition, it was shown that some species have the capacity to grow by using Extracellular Polymeric Substances (EPS) of microbial origin (dextran, pullulan, peptides, etc.) (Legin et al. 1998). So far, no respiration ability on electrode or direct EET mechanism have been reported about this archaeal genus, even if some *Thermococcus* species have been shown to reduce amorphous Fe (III) oxide. However, the mechanism is still unclear and could be mediated through electron transfer to humic substances and other extracellular quinones (Lovley et al. 2000, Slobdokin et al. 2001). Furthermore, a recent study has highlighted the possibility of hydroquinone for microbial electron transfer to electrically conductive minerals, especially with pyrite composing hydrothermal chimney, or electrode (Taran, 2017). Nevertheless, no current was obtained with replacement of electrode with spent media, indicating no mediated electron transport in our condition. However, species of *Thermococcus* genus have been reported to produce nanotubes or nanowires by budding of their cellular envelope but their function have not been fully

understood (Marguet et al. 2013). As suggested by the authors, these archaeal nanopods or nanotubes could be used to expand the metabolic sphere around cells, promote intercellular communication or act in sulfur detoxifying mechanisms (Gorlas et al. 2015). We can therefore suppose a potential role of these nanotubes in EET. Thus, *Thermococcus* sp. could potentially be exoelectrogenic microorganisms through a still unknown mechanism.

Remarkably, the obligatory presence of both *Thermococcus* and *Geoglobus* species found in each BES on the polarized electrode did not seem fortuitous. Assuming that the *Thermococcus* species found in our enrichment are heterotrophic, after consumption of YE traces, their only carbon source available would be the EPS or organic compounds produced by *Geoglobus* spp. present on polarized electrode. Then, their fermentative metabolism would lead to the production of acetate, H₂ and CO₂ which could then be used by *Geoglobus* species to grow using the electrode as the ultimate electrons acceptor. However, recent data have shown the inability of *Geoglobus* to transfer electrons to an electrode from H₂ (Yilmazel et al. 2018). Previous studies have shown that some electroactive bacteria are also able to grow syntrophically with other microorganisms via direct interspecies electron transfer (DIET) (Shrestha and Rotaru, 2014). As explained previously, *Geoglobus ahangari* has shown a weak electron transfer capacity when grown in pure culture. The higher current density obtained in our conditions would suggest that the *Geoglobus* sp. and *Thermococcales* enriched on our polarized electrodes live syntrophically to improve their growth, and subsequently increased the quantity of electrons transferred to the electrode. Thus we would suggest that there is a syntrophic mechanism, with potentially DIET, between *Thermococcus* and *Geoglobus* in deep hydrothermal vents.

4. Conclusion

This study is the first to report on the enrichment of electroactive consortium in ex-situ conditions that mimic the conductive chimney of a hydrothermal vent with polarized carbon cloth in anaerobic artificial seawater at 80 °C. Moreover, we demonstrate the specificity of enrichment of *Bacteria* on Fe (III) oxide compared to the enrichment of *Archaea* (mainly *Thermococcus* sp. and *Geoglobus*

sp.) on BES, where the biodiversity is more conserved. These results support the hypothesis of electroactivity as a well-represented metabolism in this type of environment by confirming the presence of exoelectrogenic microorganisms capable of external electron transfer to conductive support.

Figure 1: Dominant taxonomic affiliation and biodiversity indices of microbial communities from Crushed Chimney, Flask enrichment on iron (III) oxide, Electrode and Liquid media from BES1 and BES2. OTUs representing lower than 0.5% of total sequences of the sample was grouped as Rares OTU. Biodiversity indexes of Richness and Evenness represent the number of observed OTU and the Pielou's J' evenness index respectively.

Figure 2: Current monitoring (A/m²) of BES1 Enrichment inoculated with crushed hydrothermal chimney (blue line), BES2 Enrichment inoculated with flask subculture (green line) and abiotic control (orange line). Electrode potential was poised at -0.110V vs Ag/AgCl. Arrows represent the renewal of the liquid media.
