Abstract :

Ocean acidification (OA) is a major global driver that leads to substantial changes in seawater carbonate chemistry, with potentially serious consequences for calcifying organisms. Marine shelled molluscs are ecologically and economically important species, providing essential ecosystem services and food sources for other species. Due to their physiological characteristics and their use of calcium carbonate (CaCO₃) to build their shells, molluscs are among the most vulnerable invertebrates with regard to OA, with early developmental stages being particularly sensitive to pH changes. This study investigated the effects of CO₂-induced OA on juveniles of the European abalone *Haliotis tuberculata*, a commercially important gastropod species. Six-month-old juvenile abalones were cultured for 3 months at four pH levels (8.1, 7.8, 7.7, 7.6) representing current and predicted near-future conditions. Survival, growth, shell microstructure, thickness, and strength were compared across the four pH treatments. After 3 months of exposure, significant reductions in juvenile shell length, weight, and strength were revealed in the pH 7.6 treatment. Scanning electron microscopy observations also revealed modified texture and porosity of the shell mineral layers as well as alterations of the periostracum at pH 7.6 which was the only treatment with an aragonite saturation state below 1. It is concluded that low pH induces both general effects on growth mechanisms and corrosion of deposited shell in *H. tuberculata*. This will impact both the ecological role of this species and the costs of its aquaculture.

Introduction

Anthropogenic carbon dioxide emission and its subsequent absorption by the ocean is responsible for seawater pH decrease and reduced availability of carbonate ions, leading to a decrease of calcium carbonate saturation state, two processes known as ocean acidification (OA) (Doney et al. 2009; Gattuso et al. 2015; IPPC 2014). Future projections suggest that there will be a pH reduction of 0.3 units by the year 2100, threatening marine organisms that produce calcium carbonate exoskeletons and shells, such as corals, molluscs, and echinoderms (Kroeker et al. 2010; Hendricks et al. 2010; Hofmann et al. 2010; Widdicombe and Spicer 2008; Wittmann and Pörtner 2013). Because they do not compensate for acid–base disturbances, molluscs are considered to be among the most vulnerable invertebrates with respect to OA, with a pronounced sensitivity in larval and juvenile stages (Beniash et al. 2010; Gazeau et al. 2013; Melzner et al. 2009; Orr et al. 2005; Przeslawski et al. 2015, Ross et al. 2011). In marine shelled molluscs, OA has been shown to reduce larval survival, lengthen development time, alter morphology, and/or impair shell formation and calcification (Byrne et al. 2011; Duquette et al. 2017; Ellis et al. 2009; Fitzer et al. 2014a; Gazeau et al. 2010; Kurihara 2008; Noisette et al. 2014). Since many mollusc species are sources of commercially

important foods, negative impacts of OA may also result in significant economic loss (Ekstrom et al. 2015; Gazeau et al. 2007).

Abalones are ecologically and economically important shelled gastropods, which are grazers in the marine ecosystem and a food delicacy for humans (Cook 2014; Huchette and Clavier 2004). Many abalone species worldwide have experienced severe population decline due to both overfishing and environmental perturbations, such as global warming and disease (Nicolas et al. 2002; Travers et al. 2009). In the context of the growth of worldwide aquaculture (Cook 2014), understanding the effects of stress on abalone physiology would allow the farmers to adapt their practices to minimize stress, prevent mortalities, and produce higher quality shellfish (Morash and Alter 2015).

The abalone *Haliotis tuberculata* is a commercially important species, for which rearing over the whole life cycle is controlled in aquaculture (Courtois de Viçose et al. 2007). It displays a pelago-benthic life cycle with a larval planktonic stage followed by a critical metamorphosis into the benthic juvenile, making this species highly sensitive to environmental changes (Byrne et al. 2011). Several studies have focused on early life-history stages of abalone, especially on larvae, and have demonstrated adverse effects of elevated CO₂, such as reduced survival, developmental delay, body and shell abnormalities, and reduction in mineralization (Byrne et al. 2011; Crim et al. 2011; Guo et al. 2015; Kimura et al. 2011; Onitsuka et al. 2018; Wessel et al. 2018; Zippay and Hofmann 2010). Shell formation has been extensively studied in *H. tuberculata*, revealing that aragonite is the main CaCO₃ polymorph (Auzoux-Bordenave et al. 2010, 2015). Since aragonite is a less stable polymorph than calcite and is likely to be more susceptible to dissolution (Morse et al. 2007), the abalone shell is expected to be more sensitive to OA (Gazeau et al. 2013). The juvenile stage is a relevant model to study the effects of OA, since (1) it corresponds to the growing stage between larvae and adults and (2) it is a critical period where abalone are submitted to strong predation (Shepherd 1973). So far, only two studies investigated the responses of juvenile abalone to decreased seawater pH. In juvenile *Haliotis iris* from New Zealand, a significant reduction of shell growth was observed under lower pH (0.3–0.5 pH units less than the control), but no effect on respiration rate (Cunningham et al. 2016). More recently, the effects of low pH (−0.3 to −0.5 units below control pH) on juvenile *H. discus hannai* resulted in eroded shell surfaces, reduced growth rates, and altered

biochemical composition and energy metabolism (Li et al. 2018). The impact on shell microstructure or resistance to fracture was not investigated.

The goal of the present study was to investigate the effects of CO₂-induced OA on survival, growth and shell mineralization and mechanics of juveniles of the European abalone *H. tuberculata*. Six-month-old juvenile abalones were cultured for 3 months under current and near-future pH conditions (8.1, 7.8, 7.7, and 7.6). Biological responses such as survival rate, growth performance (shell length, weight, and shell growth), and shell biomineralization were compared across the different pH treatments. SEM microscopy and fracture force analyses were performed to assess whether reduced pH has an influence on shell microstructure, thickness, and resistance.

Materials and methods

Abalone collection and rearing

Farmed, 6-month-old juvenile abalones *H. tuberculata* ($n = 540$ in total, 6.0 ± 0.5 mm total shell length) were collected from nursery tanks at the France Haliotis abalone farm ($48^{\circ} 36' 46N$, $4^{\circ} 33' 30W$; Plouguerneau, France) in January 2013 and transported to the laboratory at the marine station, Concarneau (MNHN, France). The abalone were randomly distributed into 12 experimental aquaria (12 L) supplied with filtered 3 µm natural seawater renewed at a rate of 6 L h⁻¹ and aerated with ambient air. Temperature was the local value in January, i.e., $9.3^{\circ}C \pm 0.5^{\circ}C$. Animals were conditioned in the laboratory, at ambient pCO_2 , at a density of 45 abalones per aquarium, for 3 weeks. Juvenile abalone shells usually have a green coloration, resulting from their grazing on *Ulrella* sp. algae at the farm. At the start of the experiment, the abalone diet was changed from green algae *Ulrella* to red *Palmaria palmata* which is a high-quality alga giving the best growth performance for *H. tuberculata* (Mercer et al. 1993). This changeover is part of standard procedure in aquaculture when juveniles reach 6–10 mm and results in a change of shell colouration from greenish to red (Marchais et al. 2017). Shell marking by algal feeding can be used as a proxy to determine growth in long-term stock enhancement program (Gallardo et al. 2003). This transition allowed us to mark the start (T0) of the experimental period for the evaluation of shell growth. The abalones were fed once a week ad libitum with the red macroalgae *P. palmata*.

Experimental design

Experiments were carried out between March and June 2013 at the Concarneau marine station (France) according to an experimental design adapted from Martin et al. (2011). Juvenile abalones were exposed to four pH levels (total scale) for 3 months. The treatments consisted of a control at present-day pH, pH_T 8.1 ($p\text{CO}_2 \approx 400 \mu\text{atm}$), and three levels of predicted pH_T according to different climate change scenarios, as outlined in Riebesell et al. (2010): 7.8 ($p\text{CO}_2 \approx 750 \mu\text{atm}$), 7.7 ($p\text{CO}_2 \approx 1000 \mu\text{atm}$), and 7.6 ($p\text{CO}_2 \approx 1400 \mu\text{atm}$). Three replicate aquaria were set up per pH treatment.

pH control and carbonate chemistry

Low seawater pH_T levels were obtained by bubbling CO_2 (Air Liquide, France) into three 100 L header tanks supplied with filtered through-flowing seawater, continuously aerated with ambient air. Each header tank supplied three experimental 12 L aquaria at a rate of 6 L h^{-1} . $p\text{CO}_2$ in each tank was regulated through electro-valves controlled by a pH-stat system (IKS Aquastar, Germany). pH values of the IKS system were adjusted from daily measurements of the electromotive force (emf) in each aquarium using a pH meter (Metrohm 826 pH mobile, Metrohm, Switzerland) with a glass electrode (Metrohm electrode plus), converted to total scale pH units (pH_T) using Tris/HCl and 2-aminopyridine/HCl buffers (Dickson 2010). At the start of the experiment, pH was gradually decreased over 10 days by 0.05 pH unit day^{-1} until the different target pH levels were reached.

Seawater parameters were monitored throughout the 3-month experiment. Temperature and pH_T were recorded almost daily in each of the 12 experimental aquaria using a pH meter as described above. Salinity was measured twice a week using a conductivity meter (3110, WTW, Germany). Total seawater alkalinity (A_T) was measured every 2 weeks on 100 mL samples taken from each experimental aquarium. Seawater samples were filtered through 0.7 μm Whatman GF/F membranes, immediately poisoned with mercury chloride, and stored in a cool dark place pending analyses. A_T was determined potentiometrically using an automatic titrator (TitroLine alpha, Schott SI Analytics, Germany), calibrated with the National Bureau of Standards scale. A_T was calculated using a Gran function applied to pH values ranging from 3.5 to 3.0, as described by Dickson et al. (2007), and corrected by comparison with standard reference material provided by Andrew G. Dickson (CRM Batch 111). Seawater carbonate chemistry, i.e., dissolved

inorganic carbon (DIC), $p\text{CO}_2$, and aragonite saturation state ($\Omega_{\text{aragonite}}$), were calculated from pH_T , A_T , temperature, and salinity with the CO₂SYS program (Pierrot et al. 2006) using constants from Mehrbach et al. (1973) refitted by Dickson and Millero (1987).

Juvenile survival and sampling

Survival of the juvenile abalones was assessed almost daily during the 3-month experiment. Any dead individuals were removed from the tanks immediately. Mortality was calculated as the proportion of the number of dead abalones vs the total number of abalones per tank and then averaged over the three replicates to calculate the mean survival for each pH treatment. Juvenile individuals were sampled at the start of the experiment (T0) and after 3 months of exposure (T3m). Soft tissues were dissected, while shells were rinsed with distilled water, dried, and stored at room temperature until analysis.

Biometric measurements

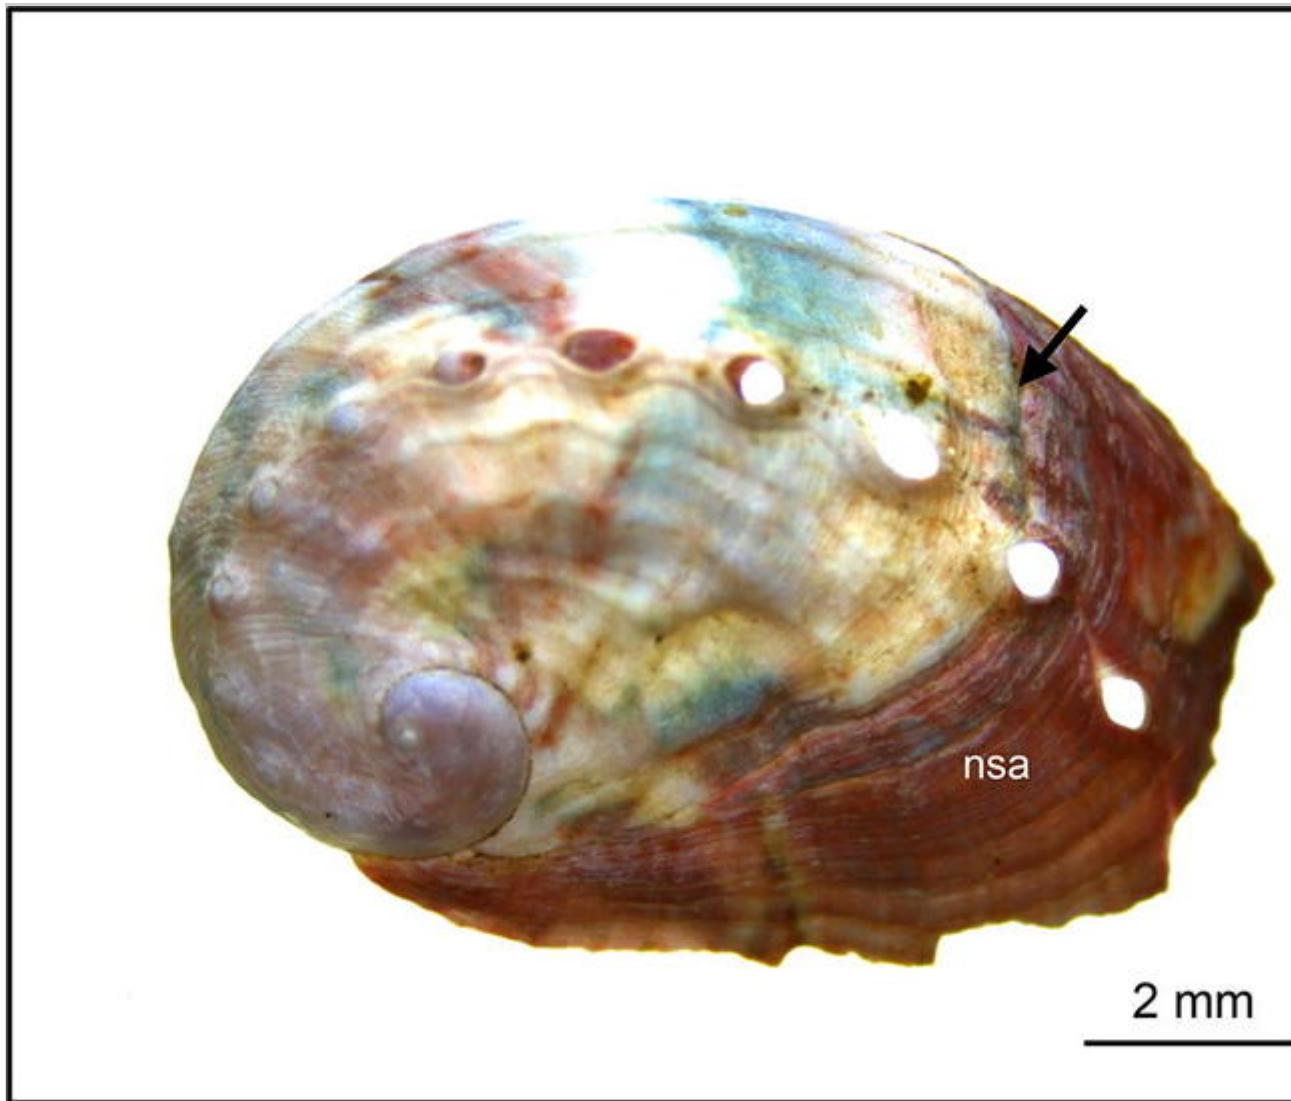

Shell length was measured with a Vernier calliper to the nearest 0.05 mm on 12 abalones from each replicate ($n = 36$ per pH treatment). Shell dry weight was measured on an analytical laboratory balance (Ohaus, Switzerland) to the nearest 0.001 mg ($n = 21$ per pH treatment, except for pH 7.6, $n = 13$). For shell weight, the lower number of individuals in pH_T 7.6 is due to the high percentage of broken shells in this condition; indeed, only the whole shells were used for shell weight determination and further SEM analysis on cross sections. The remaining shell samples were used for shell strength measurements. Shell index was calculated as the ratio total shell weight/(shell length)³ ($n = 21$ per pH treatment, except for pH 7.6, $n = 13$).

For the estimation of relative shell growth, the external mark on the shell induced by the change in algal diet (Fig. 1) was used as a proxy to estimate the shell area newly formed during the 3-month experiment. Shell surfaces were examined under a binocular microscope (Leica, Germany) and imaged with NIS elements software (Nikon, Japan). For the determination of relative shell growth, the newly formed area (red coloured) was measured by tracing its outline using Image J software. The ratio of red shell area/total shell area was calculated for each abalone shell and used as a proxy to determine relative shell growth ($n = 36$ per pH treatment). All measurements were made by a single researcher, with the origin of each shell anonymized to eliminate

subjective bias.

Fig. 1

Shell of a 9-month-old abalone showing the transition from greenish to red colouration induced by the change of algal diet (black arrow); the transition mark was used as a proxy to estimate the shell area newly (nsa) formed during the 3-month experiment

Scanning electron microscopy (SEM)

Randomly chosen abalone shells from control pH and pH 7.6 ($n = 5$ per pH treatment) were analysed by SEM. Outer and inner shell surfaces were investigated on whole, gold-coated (JEOL JFC 1200 fine coater) samples. Shell thickness and microstructure were examined on shell cross sections cut using a razor blade along the longitudinal growth axis of the shell. Samples were gold-coated (JEOL JFC 1200 fine coater) and observed at 5–15 kV with

either a JEOL JSM-840A or a Sigma 300 FE-SEM scanning electron microscope (SEM, Plateau Technique de Microscopie Electronique, MNHN, Paris and Concarneau, France). Shell thickness (total, outer spherulitic, and nacre layer thickness) measurements were made on SEM images of the cross sections using Image J software from 6 to 9 transects per shell section (Fig. S1, electronic supplementary material).

Biomechanical tests

Shell strength (resistance) of abalone shells was measured individually ($n = 10$ shells/pH treatment) using a simple compression method. The shells were placed on a metal block with the opening downwards (i.e., in what would be their natural position on a rocky substrate) and the mechanical test was carried out using a second metal block fixed on the load frame of the force stand (Instron 5543), which was then lowered onto the shell at a speed of 0.3 mm min^{-1} (simple compression test) until fracture. Displacement and force were recorded continuously at a frequency of 10 Hz using a 100 N force cell (Instron 2530-100 N). The failure force was recorded for each specimen. A representative curve of compressive force vs displacement is presented in supplementary Fig. S2. A stress–strain relationship was not established because of the absence of symmetry in the abalone shell and the difficulty to define the surface on which the force is applied.

Statistical analysis

All statistical analyses were performed with Rstudio software (R Core Team 2015). Differences in juvenile survival, shell length and weight, relative growth, and shell index across pH treatments were assessed using generalized linear model (GLM) ANOVAs after testing the normality of data, normality of residuals and homogeneity of variances (pH: fixed factor, tank: random factor nested into pH). In the few cases where data distribution deviated from normality and/or variances was not homogeneous, data were log-transformed to ensure compliance with ANOVA assumptions. If the homogeneity of variance was not verified, a Welch test was performed, as recommended by Day and Quinn (1989). Post hoc HSD Tukey tests, using the appropriate mean-square error, were used to test the differences between the group means. To detect any significant differences in shell thickness, unpaired Student's t tests were performed. To assess the effect of decreased pH on shell strength, regression analyses were performed to look at the relationships between fracture force and shell weight. ANCOVA model was used to compare linear

regression models and evaluate the effect of pH, using weight as a covariate. All data are presented as mean \pm SD, except where otherwise stated. Differences were considered significant at $P < 0.05$.

Results

Seawater parameters

Mean values of seawater carbonate chemistry parameters for the four pH treatments are given in Table 1. Seawater temperature followed the natural variations found in the bay of Concarneau, ranging from 9.3 ± 0.5 °C at the start of experiment (early March) to 16.1 ± 0.5 °C at the end (mid-June), with the mean ranging from 12.1 ± 1.8 to 12.4 ± 1.8 °C according to treatment. The pH_T of the experimental aquaria was maintained close to the nominal values throughout the experiment, at $pH_T = 8.10$ ($pCO_2 = 347 \pm 5$ µatm), $pH_T = 7.81$ ($pCO_2 = 746 \pm 10$ µatm), $pH_T = 7.73$ ($pCO_2 = 934 \pm 13$ µatm), and $pH_T = 7.65$ ($pCO_2 = 1157 \pm 35$ µatm). Mean total alkalinity (A_T) measured in the experimental aquaria ranged from 2305 ± 28 to 2312 ± 30 µEq kg⁻¹ ($n = 8$ per pH treatment) over the course of the experiment and presented only slight differences between treatments. Salinity was 35.2 ± 1.7 in all experimental aquaria. Ω_{calcite} was always greater than 1 in all four pH treatments, while $\Omega_{\text{aragonite}}$ only reached values below 1 in the lowest pH_T treatment (7.6).

Table 1

Parameters of seawater carbonate chemistry during the experiment (mean \pm SD)

Nominal pH	pH _T	Temperature (°C)	TA (µEq kg ⁻¹)	pCO ₂ (µatm)	DIC (µmol kg ⁻¹)	HCO ₃ ⁻ (µmol kg ⁻¹)
8.1	8.11 ± 0.04	12.4 ± 1.8	2305 ± 28	335 ± 33	2070 ± 22	1890 ± 35
7.8	7.81 ± 0.05	12.1 ± 1.7	2312 ± 30	750 ± 18	2209 ± 18	2088 ± 24
7.7	7.71 ± 0.04	12.3 ± 1.7	2308 ± 37	958 ± 108	2237 ± 17	2124 ± 20

pH on the total scale (pH_T), temperature (°C), salinity, and total alkalinity (µEq kg⁻¹) pressure (pCO_2 ; µatm), dissolved inorganic carbon (DIC; µmol kg⁻¹), HCO₃⁻, CO₃²⁻, ($\Omega_{\text{aragonite}}$), and calcite saturation state (Ω_{calcite}) using the CO₂SYS program. pH_T and recorded almost daily throughout the experiment ($n = 76$ per pH treatment). Salinity w 35.3 ± 1.3, $n = 26$) and total alkalinity was measured every 2 weeks throughout the ex]

Nominal pH	pH _T	Temperature (°C)	TA (μEq kg ⁻¹)	pCO ₂ (μatm)	DIC (μmol kg ⁻¹)	HCO ₃ ⁻ (μmol kg ⁻¹)
7.6	7.60 ± 0.05	12.1 ± 1.8	2309 ± 34	1259 ± 140	2274 ± 16	2164 ± 17

pH on the total scale (pH_T), temperature (°C), salinity, and total alkalinity (μEq kg⁻¹) pressure (pCO₂; μatm), dissolved inorganic carbon (DIC; μmol kg⁻¹), HCO₃⁻, CO₃²⁻, ($\Omega_{\text{aragonite}}$), and calcite saturation state (Ω_{calcite}) using the CO₂SYS program. pH_T was recorded almost daily throughout the experiment ($n = 76$ per pH treatment). Salinity was 35.3 ± 1.3, ($n = 26$) and total alkalinity was measured every 2 weeks throughout the experiment.

Survival

The mortality of juvenile abalones was very low, with a survival percentage ranging between 90.9 ± 10.3% and 96 ± 3.3% at the end of the experiment. There were no significant differences in survival among the four pH treatments [ANOVA, $F(3,8) = 0.367$, $P = 0.78$].

Shell growth

Abalones grew in all treatments, from 6.0 ± 0.5 mm at the start of the experiment to 8.3 ± 1.0 mm (pH_T 8.1), 8.7 ± 1.0 mm (pH_T 7.8), 8.1 ± 1.0 mm (pH_T 7.7), and 7.8 ± 1.1 mm (pH_T 7.6) after 3 months. Total shell length after 3 months differed significantly according to pH treatment [ANOVA, $F(3,8) = 4.78$, $P = 0.034$, Fig. 2]: juveniles exposed to pH_T 7.6 were significantly smaller than those exposed to pH_T 7.8 (Post hoc Tukey, $t_8 = -3.656$, $P = 0.027$, Table 2). No significant differences were observed between juveniles exposed to pH_T 7.7, 7.8 and the control pH_T (8.1).

Fig. 2

Shell length of juvenile abalones *H. tuberculata* exposed to decreased pH_T values. Centre lines of box plots show the medians; box limits indicate the first and third quartiles, respectively, with whiskers encompassing data within 1.5 times the spread from the median ($n = 36$ per pH treatment). Different letters indicate significant differences between pH treatments ($P < 0.05$)

Shell weight was significantly affected by pH [ANOVA, $F(3,8) = 24.43$, $P < 0.001$, Fig. 3], being lower for juveniles exposed to pH_T 7.6 compared with those grown in other pH treatments (post hoc Tukey, $P < 0.005$, Table 2). Relative shell growth, determined as the ratio of red shell area/total shell area, did not differ significantly between pH treatments [ANOVA, $F(3,8) = 0.626$, $P = 0.618$, Table 2].

Fig. 3

Shell weight of juvenile abalones *H. tuberculata* exposed to decreased pH_T

values. Centre lines of box plots show the medians; box limits indicate the first and third quartiles, respectively, with whiskers encompassing data within 1.5 times the spread from the median ($n=22$ per pH treatment, except for pH 7.6 $n=13$). Different letters indicate significant differences between pH treatments ($P<0.05$)

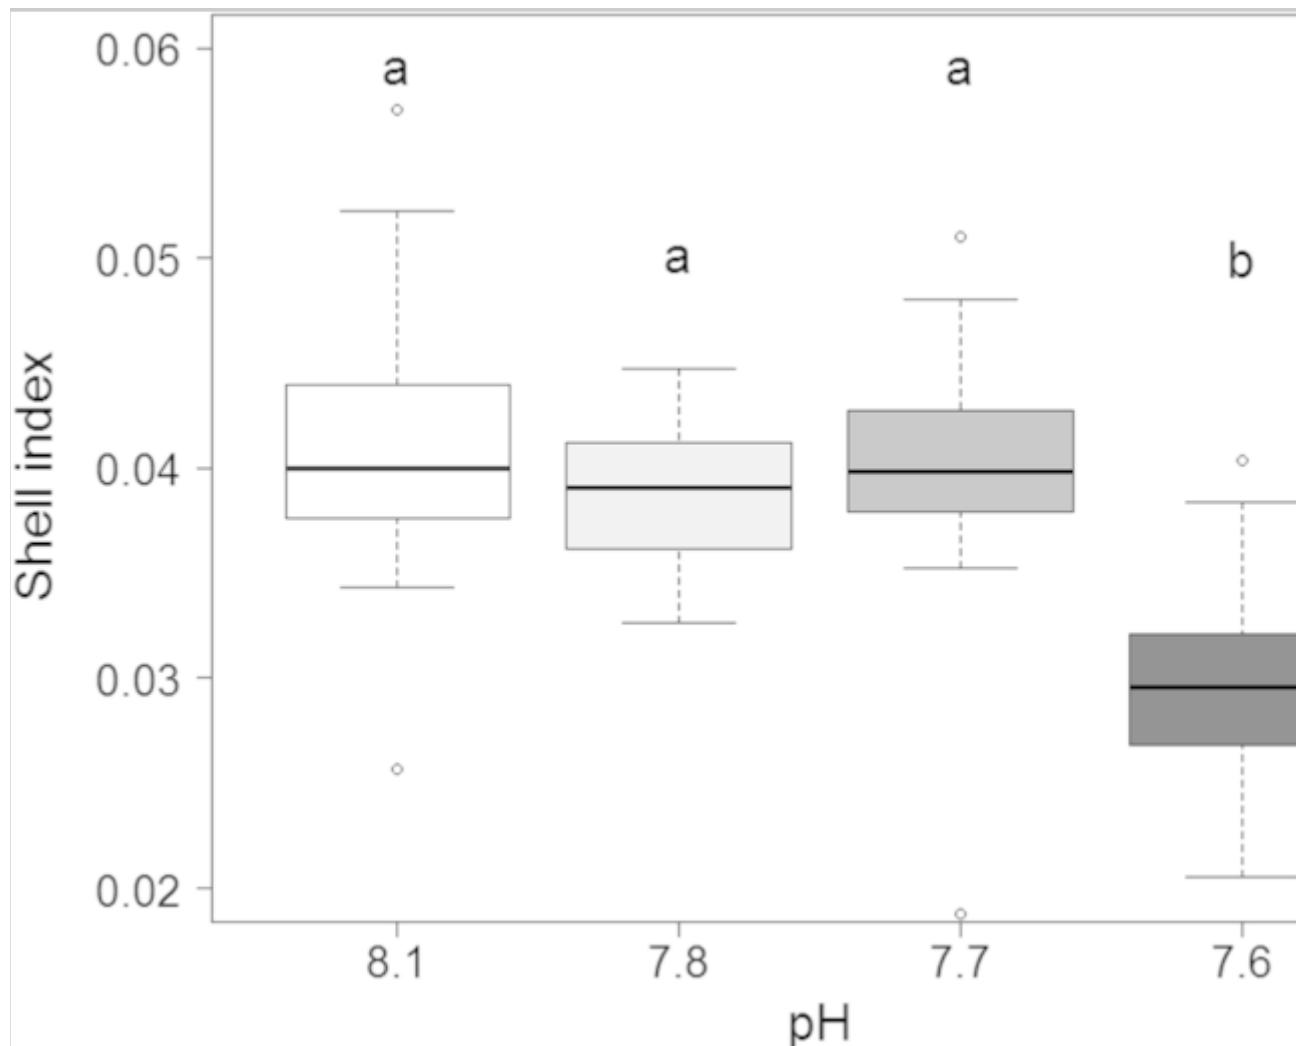

Shell calcification

Shell index was significantly affected by pH [Welch's F test, $F(3, 3.982) = 14.48, P = 0.013$; Fig. 4]. Abalones in the pH_T 7.6 treatment had a reduced shell index compared to those grown in the other pH treatments ($P < 0.005$, Table 2).

Fig. 4

Shell index (determined as the ratio shell weight/shell length³) of juvenile abalones under different pH_T conditions. Centre lines of box plots show the medians; box limits indicate the first and third quartiles, respectively, with

whiskers encompassing data within 1.5 times the spread from the median ($n=22$ per pH treatment, except for $\text{pH}_T 7.6 n=13$). Different letters indicate significant differences between pH treatments ($P<0.05$)

SEM examination of abalone shells grown at $\text{pH}_T 8.1$ and 7.6 revealed differences in the texture and porosity of both outer and inner surface layers. Under control conditions, almost intact periostracum were observed with typical ornamentations (ridge and groove pattern) and regular organic sheets (Fig. 5a, c). At lower pH, the periostracum revealed bleached areas and a corroded surface with numerous small holes (Fig. 5b, d). In some individuals, large holes were observed between the apertures as a result of shell corrosion (Fig. 5b). The delamination of surface organic sheets revealed biominerals of the underlying spherulitic layer (Fig. 5d). In control shells, the inner nacreous layer had a homogeneous surface, with a gradual maturation of aragonite platelets (Fig. 6a, c, e). By contrast, juvenile shells from the low pH treatment (pH 7.6) were characterized by a partial degradation of the inner nacreous

layer, resulting in decreased size of aragonite platelets and irregularities of their edges (Fig. 6b, d, f).

Fig. 5

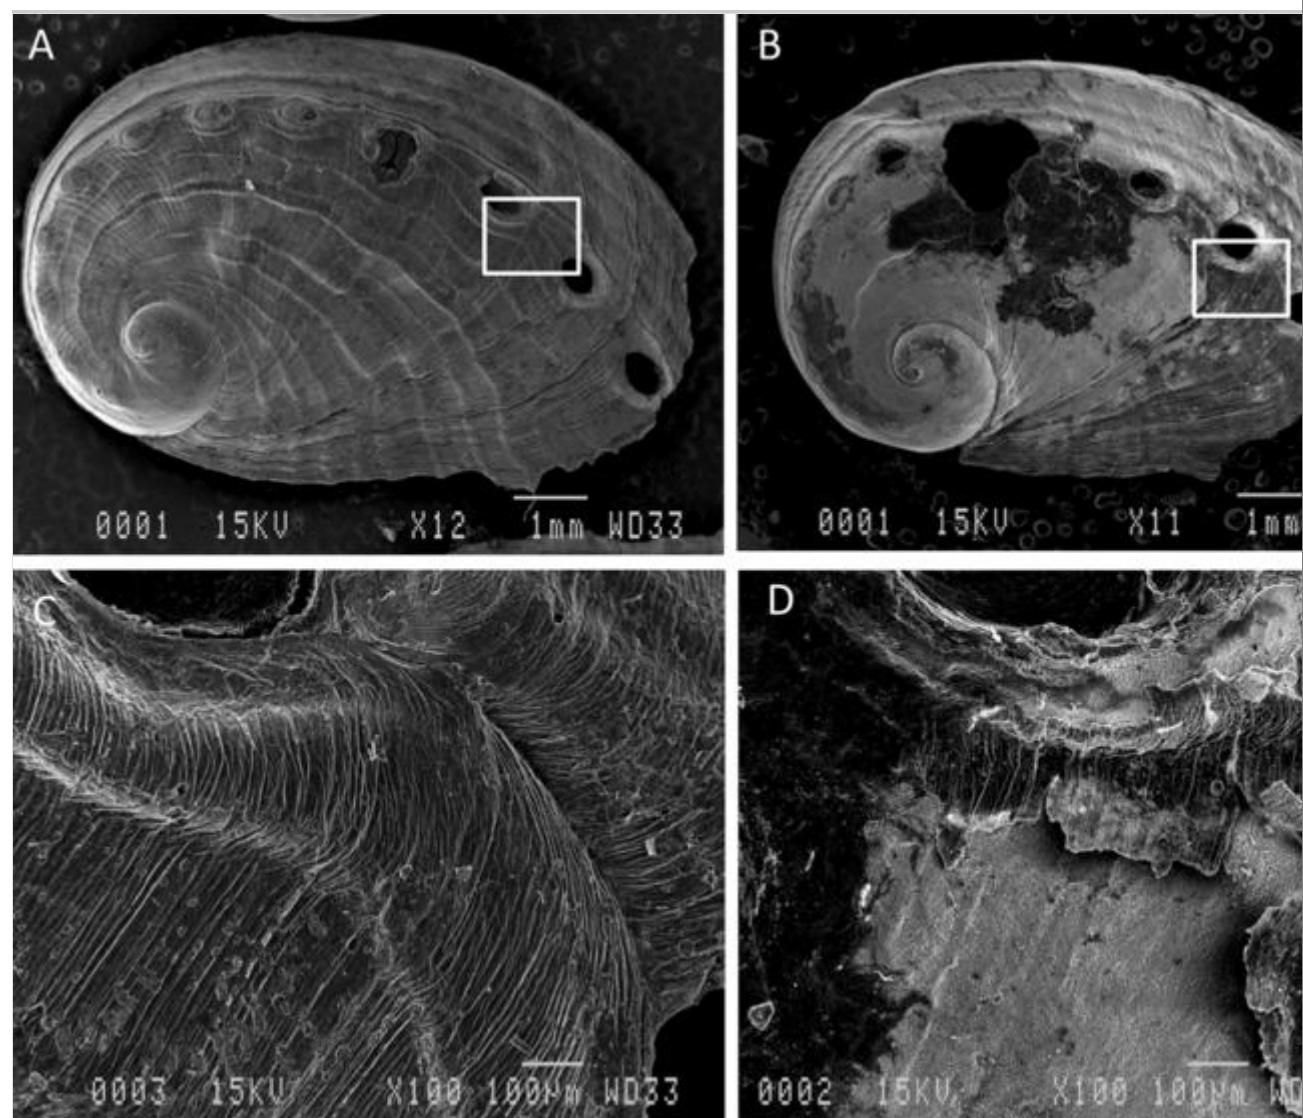

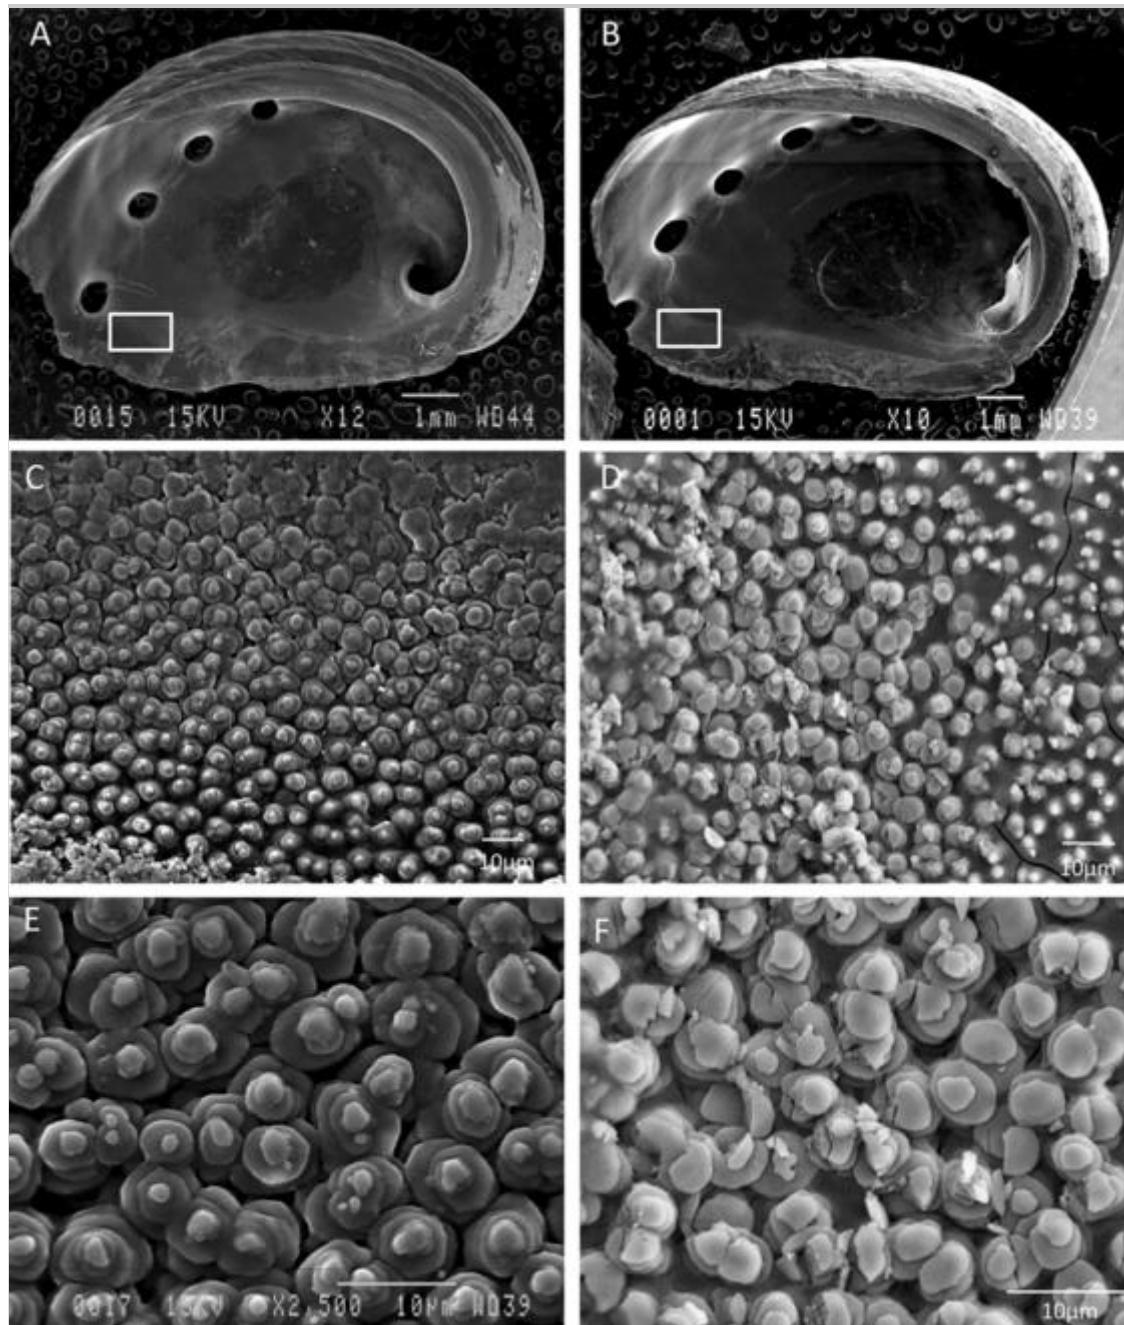

Fig. 6

SEM images of abalone inner nacreous surface in control conditions (pH_T 8.1: **a, c, e**) and under low pH_T 7.6 (**b, d, f**). **a** Inner nacreous layer of control shell; **b** inner nacreous layer of shell exposed to pH_T 7.6; **c** detail of the nacre growth

region boxed in **A** showing gradual maturation of aragonite platelets; **d** detail of the nacre surface boxed in **b** showing disruption of the aragonite platelets; **e** magnification of the nacre surface showing confluence of regular aragonite platelets; **f** magnification of the nacre platelets showing breaks within the platelets and irregularities of their edges

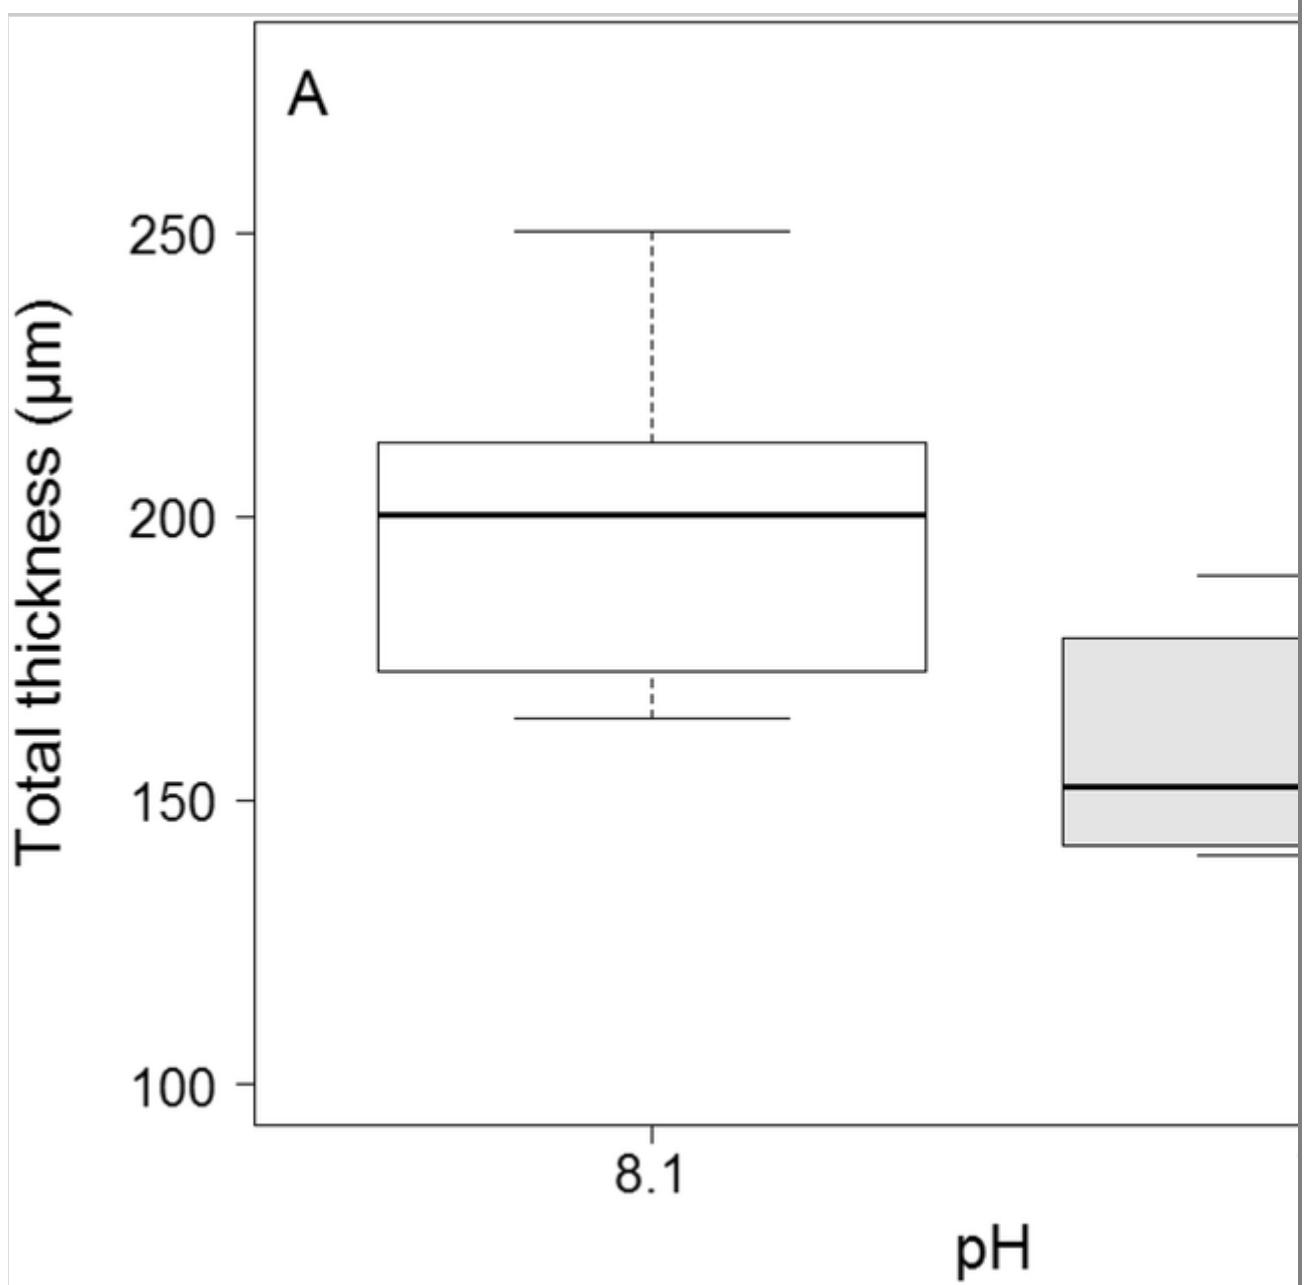

Measurements along the shell section showed a progressive decrease of total shell thickness from older to newly formed shell regions (results not shown), which is in accordance with the shell growth process. Total shell thickness tended to be smaller in juveniles exposed to pH 7.6 compared with those reared under control pH_T (unpaired *t* test, $t_8 = -2.1644$, $P = 0.062$, Fig. 7a).

However, a significant reduction of the spherulitic layer thickness was observed at pH_T 7.6 compared with the control group (unpaired t test, $t_8 = -2.8522$, $P = 0.021$, Fig. 7b). There was no significant differences in nacre shell thickness between abalones grown in these two pH treatments (unpaired t test, $t_8 = -0.4381$, $P = 0.67$).

Fig. 7

Total thickness (**a**) and spherulitic layer thickness (**b**) of juvenile abalone shells grown under control pH_T (8.1) and low pH_T (7.6) treatment. Centre lines of box plots show the medians; box limits indicate the first and third quartiles, respectively, with whiskers encompassing data within 1.5 times the spread from the median ($n = 5$ per pH condition). Asterisk indicates a significant difference between pH treatments (unpaired Student's t test, $P < 0.05$)

The shell fracture force was significantly lowered at pH_T 7.6 compared with shells that had grown in the three other pH treatments [ANOVA, $F(3,7) = 11.15, P = 0.0047$, Fig. 8, Table 3]. However, because shell weight (and thickness) was reduced at low pH, the fracture force was analysed according to weight. The regression of shell fracture force on abalone shell weight showed a linear relationship [linear regression, $r^2 = 0.63, F(1,41) = 68.42, P = 0.031$, Fig. 9]. A test of homogeneity of slopes of the regression lines of shell fracture force vs weight showed that these were not significantly different between pH treatments [interaction pH \times weight, $F(3,34) = 0.486, P = 0.69$, Table 4]. Testing on the intercept with shell weight as a co-variable showed that the effect of pH on shell fracture force was not significant [ANCOVA, $F(3,7) = 1.021, P = 0.44$]. This indicates that the decreased fracture force at

pH_T 7.6 could be explained by the reduced amount of shell material only.

Fig. 8

Fracture force of the shells of abalones reared under different pH conditions. Centre lines of box plots show the medians; box limits indicate the first and third quartiles, respectively, with whiskers encompassing data within 1.5 times the spread from the median ($n = 12$ for pH_T 8.1 and 7.8; $n = 11$ for pH_T 7.7; $n = 7$ for pH_T 7.6). Different letters indicate significant differences between pH treatments ($P < 0.05$)

Discussion

The present study demonstrated that decreased pH negatively impacts the

growth and shell mineralization of juvenile European abalone *H. tuberculata*. Almost all the tested variables were significantly reduced at pH_T 7.6 (0.5 units below control pH), while pH_T 7.7 and 7.8 did not affect juvenile growth. These results are rather similar to those obtained in two other species of farmed abalone. In juvenile *H. iris*, Cunningham et al. (2016) reported significant effects on shell length and wet weight at pH_{NBS} 7.6 in winter (corresponding to pH_T 7.5) and at pH_{NBS} 7.8 (pH_T 7.7; 0.3 units below control pH) and 7.6 (pH_T 7.5; 0.5 units below control pH) in summer. Similarly, shell growth and shell weight were significantly lower in juvenile *H. discus hannai* after 3 months of exposure to pH_{NBS} 7.7 and 7.9 (corresponding, respectively, to pH_T 7.8 and 7.6, Li et al. 2018). These results are also in accordance with the previous studies on other marine shelled mollusc taxa, showing significant reductions in shell growth following medium-to-long-term exposure to near-future pH (reviewed in Gazeau et al. 2013). In a 2-month experiment, Thomsen and Melzner (2010) observed significant decreases in both shell mass and shell length in blue mussels exposed to lowered pH (−0.3 to −0.9 units). Similarly, the mussel *Mytilus galloprovincialis* exhibited a slow down of shell growth when pH was reduced by 0.75 units, possibly caused by dissolution (Michaelidis et al. 2005). As suggested in the previous studies, the effects of OA on shell growth and calcification would result either from a direct effect on CaCO_3 dissolution or from indirect metabolic effects, such as physiological and molecular processes regulating shell biomineralization (Beniash et al. 2010; Hüning et al. 2012; Klok et al. 2014). The increasing cost of maintaining acid–base balance combined with an impaired ability to calcify under OA may explain the decrease in the scope for growth among early life stages of molluscs experiencing acidified conditions (Gazeau et al. 2013; Parker et al. 2013; Thomsen et al. 2015). However, Cunningham et al. (2016) found no changes in respiration rate of *H. iris* juveniles subjected to reduced pH (−0.3 to −0.5 units), indicating that abalones do not up-regulate their metabolism. Nothing is known on the acid–base balance regulation abilities of abalones but molluscs (apart from cephalopods) are usually considered to have a poor ability to compensate for decreasing haemolymph pH in situations of seawater acidification (Melzner et al. 2009). According to Cyronak et al. (2016), elevated H^+ concentration and subsequent problems of homeostasis rather than carbonate ions concentration would be more likely responsible for the reduction of calcification in marine organisms facing OA.

Our results revealed significant changes in shell microstructure of juvenile abalones grown at pH_T 7.6, including corrosion of the outer periostracum and

degradation of the inner nacreous aragonite layer. In juvenile *H. discus hannai*, corroded periostracum was found in individuals grown at pH_{NBS} 7.7 (Li et al. 2018), but the effect of decreased pH on shell microstructure was not investigated. Shell surface corrosion and changes in biomineral microstructure under low pH have been previously reported in juvenile bivalves and related to a direct effect on shell dissolution (Fitzer et al. 2014b; Hiebenthal et al. 2013; McClintock et al. 2009; Melzner et al. 2011; Waldbusser et al. 2011). It is noteworthy that we only recorded significant effects at pH_T 7.6, the only treatment at which $\Omega_{\text{aragonite}}$ was lower than one. The corrosion of the periostracum and degradation of the nacreous layer were observed both in the old part and in the newly formed shell under the low pH, indicating that direct dissolution is involved rather than indirect metabolic process affecting the synthesis of the new shell. However, the energetic cost for proton elimination during CaCO₃ precipitation is increased under elevated $p\text{CO}_2$, suggesting a metabolic effect.

This finding also supports the hypothesis that the effects on shell length and weight may be mainly due to the shell dissolution. Indeed, the juvenile and adult shells of *H. tuberculata* consist of two biomineralized layers, the outer spherulitic and the inner nacreous layers, both composed of the aragonite CaCO₃ polymorph (Auzoux-Bordenave et al. 2010, 2015; Jardillier et al. 2008). The predominance of aragonite in the *H. tuberculata* shell makes the species more susceptible to dissolution than other mollusc species with calcitic shells or a calcite/aragonite mixture (Gazeau et al. 2013; Parker et al. 2013). In the course of a trans-generational experiment on juvenile *M. edulis* exposed to elevated $p\text{CO}_2$, Fitzer et al. (2014a) revealed that mussels at high $p\text{CO}_2$ (1000 μatm) did not produce aragonite, which is more vulnerable to carbonate under-saturation than calcite. Under lower $p\text{CO}_2$ (550, 750 μatm), the nacreous tablets formed the usual ‘brick wall’ structure, although the nacre crystals appeared corroded and were not so closely stacked together as under normal conditions (Fitzer et al. 2014a). This could indicate reduced biological control over biomineralization of aragonite by the organism and potentially raises questions about the integrity of mollusc shells composed only of aragonite under OA.

In addition to changes in shell microstructure, we found a significant reduction in the spherulitic shell thickness and, to a lesser extent, in the total thickness of abalone shells grown at pH_T 7.6. The reduction of shell thickness is likely due to CaCO₃ dissolution of the outer aragonite layer, which would

be more sensitive to OA after periostracum corrosion. In juvenile shells of *M. edulis*, a reduction in shell thickness was reported in the aragonite layer, but not in the calcite layer, after 6 months of exposure to elevated $p\text{CO}_2$ (Fitzer et al. 2014b). Other juvenile bivalves (*Argopecten irradians* and *Mercenaria mercenaria*) grown under increased CO_2 concentration (corresponding to a reduction of 0.4–0.6 pH units) also exhibited malformed and corroded shells with reduced thickness (Talmage and Gobler 2010). Welladsen et al. (2010) also reported a significant decrease in shell strength and nacre malformation in the adult pearl oyster *Pinctada fucata* exposed to acidified seawater (pH_{NBS} 7.6), suggesting shell dissolution.

The integrity of the periostracum (the organic coating of the mollusc shell) is very important for protecting the shell from corrosion induced by low pH (Thomsen et al. 2010). In juvenile abalone, we found that the periostracum was damaged under low pH, resulting in a higher vulnerability of the underlying mineralized layers. Indeed, a subsequent reduction in thickness of the spherulitic layer as well as changes in the nacreous layer microstructure were observed. These observations are consistent with those reported for other shellfish reared under lowered pH (Talmage and Gobler 2010). All of this suggests that processes leading to the synthesis of the periostracum are affected by low pH, implying that the kinetics of aragonite precipitation (evidenced by the reduced growth rate) and the thermodynamics of its dissolution (due to under saturated sea water in the pH_T 7.6 treatment) are not the only aspects of the shell being affected. Potential effects of decreased pH on shell organic components (chitin and matrix proteins) may explain the corrosion of the periostracum and some of the changes observed in the nacre microstructure, but the underlying mechanisms are far from being understood (Fitzer et al. 2014b; Hüning et al. 2012). A number of indirect biological processes involved in shell calcification, such as matrix protein production, chitin synthesis, and enzymatic control, are influenced by changes in seawater $p\text{CO}_2$ (Weiss et al. 2013). In the mussel *M. edulis*, 6 months of incubation at 750 μatm $p\text{CO}_2$ (pH_T 7.5) significantly reduced carbonic anhydrase activity within the mantle tissue, explaining shell growth reduction (Fitzer et al. 2014b). In another study of *M. edulis*, a strong depression in the expression of mRNA for a chitinase, an enzyme involved in the calcification process, was correlated with a linear decrease in shell growth (Hüning et al. 2012). Interestingly, this study also found that expression of several genes, including some genes involved in shell protection and/or periostracum formation (tyrosinase) increased in response to elevated $p\text{CO}_2$ (Hüning et al. 2012). By

contrast, despite evidence of shell dissolution, no difference was found in the organic content or periostracum integrity of adult *P. fucata* shells exposed to pH_{NBS} 7.6 (Welladsen et al. 2010). However, the authors noted that because the study was conducted over only a 28-day period, it did not allow acclimation of the oysters to the acidified conditions.

In juvenile *H. tuberculata*, the significant reduction in shell fracture force at pH_T 7.6 can be explained by the reduced shell weight. This probably results from both reduced growth and shell dissolution. A smaller (isometric) dome is submitted to a higher meridional compressive stress for the same external force applied and will, therefore, rupture at a lower applied force (Vogel 2003). Shell dissolution will induce an easier induction of cracks and cleavage, probably initiated by dissolution pits inducing stress concentration at their level (McNeill 1968). Both effects would increase the period during which abalone are exposed to strong predation pressure before they reach a refuge in size and shell strength. This would have an economic impact on abalone aquaculture as it would increase the time required to reach a marketable size and possibly enhance productivity losses through shell breakage during handling.

Marine molluscs exert a strong control on the calcification process, but their capacities to maintain optimal conditions at the site of calcification when facing OA stress remain largely unknown (Gazeau et al. 2013; Parker et al. 2013). Because shell calcification has a high energetic cost and is very sensitive to OA (especially in early stages), energy usually allocated to growth and reproduction might be partially reallocated to calcification (Thomsen and Melzner 2010). The capacity of abalone to grow in the near future will depend on their potential to maintain their vital functions (reproduction, growth, and biomineralization) under modified environmental conditions. Since responses to OA may also differ according to differences in physiology, habitat, and behaviour of the species (Gazeau et al. 2013), the local seasonal variations in physico-chemical conditions should be considered in further studies on adaptive responses. The seawater pH_T along the Brittany coast in France naturally varies from 7.9 to 8.2 (Qui-Minet et al. 2018), so that a future scenario testing a decrease of – 0.3 units from ambient pH_T is consistent with seasonal or diurnal variations presently experienced by abalone in the tidal zone. Indeed, seasonal variations in pH are close to 0.3 units in shallow subtidal environments (Qui-Minet et al. 2018), while diurnal variations of pH_T in the intertidal zone can be higher. For instance, pH can fall

down to pH_T 7.5 in rock pools along the Brittany coast during night-time emersion at low tide (Legrand et al. 2018). Thus, abalone from Brittany shoreline environments might already experience chronically pH similar to global average pH levels predicted for open ocean by 2100 (i.e., pH_T 7.7). Such fluctuations of pH in their coastal habitats might explain the potential resistance of abalone to $\text{pH}_T > 7.6$.

The results of our study indicate that a decrease of 0.5 pH units significantly reduces growth, shell calcification and shell strength of juvenile abalone *H. tuberculata*. In the natural environment, where juvenile stages are exposed to a strong predation pressure, abalone may be at greater risk under future pH conditions as their shells may not offer sufficient protection from predators and other external stressors. Understanding how different abalone life stages respond to OA will make it possible to identify bottlenecks for population persistence under near-future pH conditions. These findings also highlight the importance of monitoring seawater parameters in aquaculture systems, where effort can be directed to maintaining seawater pH at key periods of abalone culture to minimize stress and prevent production losses.
