Abstract :

Sharks play important functional roles in coral reef ecosystems. Studying reef shark populations' spatial ecology also contributes important data for effective conservation planning. The purpose of this study was to define the home range of neonatal blacktip reef sharks (*Carcharhinus melanopterus*) around Moorea, French Polynesia, and compare estimates using both mark-recapture surveys and active acoustic telemetry. Mark-recapture surveys produced a minimum convex polygon (MCP) of 0.07 km² that was significantly larger than the MCP derived from acoustic telemetry (0.02 km²). Acoustic telemetry produced 50 and 95% kernel utilization densities that were smaller (0.02 km²) and larger (0.14 km²) than home range estimates from mark-recapture surveys, respectively. Home range estimates from this study are the smallest that have been documented for neonatal blacktip reef sharks, possibly owing to the study sites' proximity to deep channels. Mark-recapture and active acoustic telemetry are complementary approaches worthy of consideration where passive telemetry is impractical

Keywords : Elasmobranch, French Polynesia, Kernel utilization density, Marine protected area, Minimum convex polygon, Shark nursery area

Introduction

As mesopredators and apex predators, reef sharks play significant functional roles in coral reef ecosystems by exerting top-down control on lower trophic levels (e.g., consumption, fear effects; Roff et al. 2016). Individual sharks can be highly resident (Chin et al. 2016; Mourier et al. 2016) and rely on adjacent, coastal habitats as nursery areas (Heupel et al. 2018). Maintaining healthy reef shark populations has quantifiable benefits for coral reef ecosystem health (Ruppert et al. 2013; Williams et al. 2018). Therefore, identifying key habitats for reef shark populations and describing their use will contribute to more effective conservation planning with the potential for coral reef ecosystem benefits.

An animal's home range represents the area it uses for routine activity over various temporal scales. Exploring an animal's home range offers insight into species' spatial ecology and provides critical information for conservation planning (Oh et al. 2017a). Estimates of home range are typically quantified when exploring habitat use by sharks (Morrissey and Gruber 1993), and this is usually investigated *via* passive acoustic telemetry (Heupel et al. 2004). However, structurally complex coral reefs or shallow sandflats where reef sharks are observed can attenuate acoustic signals and reduce the efficacy of acoustic telemetry arrays (Heupel et al. 2006). Active acoustic telemetry techniques can overcome signal issues of passive arrays by generating short-term tracks (hours-to-days) of individuals that are closely followed (e.g., by boat or kayak; George et al. 2019). Where acoustic telemetry techniques are not possible, alternative methods for estimating home range, such as mark-recapture surveys, should be considered.

The purpose of this study was to determine habitat use of reef shark neonates within a barrier reef-fringed lagoon. Our first study objective was to compare the home range of neonatal blacktip reef sharks (*Carcharhinus melanopterus*) within the lagoon surrounding the island of Moorea, French Polynesia as estimated using mark-recapture surveys and acoustic telemetry. By validating an alternative approach to characterizing home range, we hope to offer a tested tool for use in habitats where conventional acoustic telemetry techniques are not viable. Our second objective was to observe whether

neonates' home range is constrained by deeper habitats such as a dredged boating channel bordering the study site, to suggest whether human action could artificially affect home range. This study has local significance to planning Moorea's marine protected areas (MPAs) and global significance to understanding consequences of habitat loss on the spatial ecology of a coral reef predator.

Materials and methods

Study site and animals

Research was approved by the Ministère de la Promotion des Langues, de la Culture, de la Communication, et de l'Environnement (Arrêté n°9524) of French Polynesia. Neonates were sampled from Tepee, a potential shark nursery area (17°29'22" S, 149°54'15" W), and Tiki (17°31'7" S, 149°54'45" W). The total area of Tepee, the main study site, is 0.3 km² and is delineated by natural and dredged boating channels (Figure 1); the artificial channel accounts for 11% of the area of Tepee. Both sites are shallow (~ 50 cm depth), comprising 56-59% homogenous coral and sand substrate, 19-34% coral cover, and seasonal water temperatures ranging from 25 °C (winter) to 30 °C (summer). There is a stingray (*Pateobatis fai*) provisioning site within Tepee that is associated with high adult blacktip reef shark abundance (Kiszka et al. 2016). Both Tepee and Tiki are contained within Moorea's MPA network.

Mark-recapture survey

Home range of sharks at Tepee was first estimated *via* mark-recapture survey. Sharks were captured using a gill-net (35 m length by 1.5 m depth; 5 cm mesh size) set perpendicular to shore from February to May 2012. Six fishing locations were selected that were approximately 200-600 m apart, dividing the Tepee area into five sections (Figure 1). An initial site (T1) was fished heavily at the start of the study to mark animals for recapture. All other sites were then fished haphazardly, at least three times, to observe how far sharks could be recaptured from T1. Home range was quantified using minimum convex polygons (MCPs, in km²). Conventional MCPs could not be derived because mark-recapture yielded two locations per individual. Instead, MCPs were quantified as the area in Tepee between capture

locations that was bound by the shoreline and channels, based on the *a priori* assumption that sharks did not swim into deeper water. Analyses were conducted using the Environment for Visualizing Images software (ENVI 4.8, Harris Geospatial Solutions, Inc., Broomfield, CO, USA).

Acoustic telemetry

For telemetry surveys, sharks were attracted to gill-nets with bait and captured from Tepee at dawn (04:00-07:00) from February to May 2013. Acoustic transmitters (V8 coded transmitter, Vemco, Bedford, Nova Scotia, Canada) were surgically implanted in the body cavity of neonatal sharks while they were held in tonic immobility (Kessel et al. 2015). Transmitters operated at 69 kHz (160-day battery life), transmitted signals every 16 s during the initial 72 h (then every 70 s), and weighed 0.9 g in water (< 0.1% mass of a 1.0 kg shark). Surgeries only lasted several minutes, and sharks were retained for at least five minutes following surgery to verify signal detection and ensure animals were in good condition for release. Sharks were then tracked for 24 h immediately following tagging using a kayak (Meyer and Holland 2001). Attempts were also made, 72 h post-tagging, to track sharks for an additional 12 h. Acoustic signals were detected with a VH165 omnidirectional hydrophone and VR100 receiver (Vemco, Bedford, Nova Scotia, Canada). Signals could be detected up to 50 m in > 50 cm of water over sand substrate; coral heads, strong currents, and rain reduced signal detection down to 2.0 m. Sharks were also acoustically tracked on the island's west coast at Tiki to supplement low sample sizes from Tepee. Minimum convex polygons and core (50%) and extent (95%) kernel utilization densities (KUD, km²) were estimated to quantify home range in Tepee and Tiki using the “adehabitatHR” package in R (Calenge 2006). After describing sharks' home range, we tested the hypothesis that MCP, as calculated by mark-recapture and acoustic telemetry, would not differ. Comparisons between the two methods were made using a Welch two-sample *t*-test and only for sharks from Tepee. The type-I error rate was $\alpha = 0.05$, and analyses were conducted in R (R Core Team 2018).

Results and discussion

Blacktip reef sharks' home range could be estimated using both methods (Table 1). Home range for mark-recapture was estimated from only seven of 35 sharks ($TL = 62.5 \pm 4.2$ cm; mean \pm SD) that were recaptured at Tepee at a site other than T1 after 10-45 days at liberty. Three sharks were caught between sites T1 and T4 ($MCP = 0.107$ km²) and four sharks were caught between fishing sites T1 and T3 ($MCP = 0.046$ km²; Figure 1). Active tracking of six sharks – four of seven from Tepee and two from Tiki (total length, $TL = 65.1 \pm 4.3$ cm) – yielded 12-100 detections over at least 72 hours. Core (50% KUD) habitat use was 0.024 ± 0.016 km² and extent (95% KUD) habitat use was 0.143 ± 0.142 km². Neonates at both sites remained in shallow areas with coral cover, avoiding deep channels and exposed sandflats. Previous studies suggest that neonatal blacktip reef sharks appear to prefer shallow, sheltered habitats (Oh et al. 2017b; George et al. 2019). Indeed, this is a possible predator avoidance strategy, especially because there are high densities of adult blacktip reef sharks near a stingray provisioning site at Tepee (Kiszka et al. 2016). Alternatively, neonates may engage in bold, exploratory behaviors, as one of the four sharks tracked at Tepee crossed the artificial boating channel to the east and spent the night swimming over sand substrate on the edge of this channel (Figure 2).

Mark-recapture surveys estimated larger home ranges than acoustic telemetry for sharks at Tepee. Mean MCP from mark-recapture surveys was significantly higher than mean MCP from acoustic telemetry (0.072 ± 0.012 km² SEM and 0.017 ± 0.005 km² SEM, respectively; $t = 4.03$, $df = 8$, $p = 0.003$). Acoustically tracked sharks did not swim west of T3. It is unclear, however, whether mark-recapture overestimated MCP, or if acoustic telemetry underestimated MCP. One shark's 95% KUD was greater than the area of Tepee (Table 1); although, no shark was tracked outside of the MPA containing Tepee. Mark-recapture did not allow us to estimate KUDs; although, this approach could also be used to calculate the maximum linear dimension metric (Papastamatiou et al. 2009). Further, MCP from mark-recapture will be influenced by the distance between nets (i.e., 200-600 m) and barriers (e.g., coastline, channels). For instance, our *a priori* assumption of deep-water barriers may have led to underestimation;

indeed, one shark was tracked outside the assumed area of Tepee. Further, animals' time-at-liberty (10-45 days for mark-recapture *vs.* 3 days for acoustic telemetry) could affect comparisons of MCP because blacktip reef sharks increase their home range as they grow (Oh et al. 2017b; Schlaff et al. 2017).

Neonates tracked in this study exhibited much smaller home ranges than blacktip reef shark neonates from other populations (Papastamatiou et al. 2009; Chin et al. 2016; Oh et al. 2017b). Home ranges of blacktip reef sharks (TL = 100.0 ± 17.0 cm) at Palmyra Atoll were actively monitored for 4-72 hours and had 95% KUDs of 0.5 ± 0.2 km² (Papastamatiou et al. 2009). Differences in home ranges between individuals monitored in this study and the population at Palmyra, which were tracked over similar durations, could reflect differences in habitat availability between high island narrow lagoon and atoll systems. Neonates and juveniles (TL = 73.2 ± 10.5 cm) tracked passively in Cleveland Bay, Australia over 666-779 days had 50% and 95% KUDs of 3.3 and 19.4 km², respectively (Chin et al. 2016), and neonates (TL = 63.9 ± 16.7 cm) from Mangrove Bay, Australia that were passively monitored from 2-407 days and had 50% and 95% KUDs of 1.6 ± 2.0 km² and 11.2 ± 12.5 km², respectively (Oh et al. 2017b). Here, it is possible that ontogenetic effects on home range, where sharks increase home range with size, explain the differences observed between individuals monitored for our study and the Australian populations in addition to differences in habitat availability. Indeed, proximity to deep water and abundant predators and ontogenetic stage (i.e., neonate) of individuals monitored in this study may explain the very small home ranges observed for blacktip reef sharks around Moorea.

In conclusion, our study provides preliminary insight into habitat use of reef shark neonates within Moorea's barrier reef-fringed lagoon. In fulfilling our first objective, we report the smallest home range estimates for neonatal blacktip reef sharks to date and demonstrate that active acoustic telemetry and mark-recapture surveys yielded different, but complementary results. As such, we recommend a combination of these approaches for comprehensive estimation of home range where conventional passive acoustic telemetry is impractical. Regarding our second objective, individual sharks were actively tracked almost exclusively in sheltered habitats with coral cover, demonstrating avoidance of boating

channels that may restrict home ranges. Small home ranges and nearshore distributions may disproportionately expose animals, such as neonatal blacktip reef sharks, to increased intra-specific competition over limited resources and anthropogenic disturbances, including noise pollution from boats or provisioning of larger sharks. Home range estimates of blacktip reef sharks derived from this study should be considered in future conservation planning in French Polynesia.
