### Abstract :

Studies investigating the structure and diversity of Earth's record of life older than 3.2 Ga are restricted to two locations worldwide in which sedimentary rocks have escaped regional high-grade metamorphism and penetrative deformation: the Pilbara Craton of Western Australia and the Barberton Greenstone Belt in the Kaapvaal Craton of South Africa. This paper provides a South African perspective on the evidence of Paleoproterozoic life; a record that is often overlooked in the literature. It aims to summarize and critically review previously reported claims of early life in the BGB, gives an overview of the latest findings, and provides an outlook on potential future discoveries.

The similar to 15 km thick, volcanic-sedimentary succession making up the Barberton Supergroup was deposited between 3.55 to ca. 3.20 Ga and can be subdivided in three stratigraphic units that provide a unique window into a diverse and widespread Paleoproterozoic microbial ecosystem landscape. Putative biosignatures occur almost throughout the entire BGB stratigraphy and range from carbonaceous cherts containing filamentous, spheroidal, and lenticular microstructures, traces of hydrothermal biofilms, photosynthetic microbial mats, remnants of pseudocolumnar stromatolites, and large, organic-walled spheroidal microfossils of currently unknown affinity. The BGB also contains one of the world's oldest known record of tufted microbial mats, which extensively colonized tidally-influenced, siliciclastic shorelines and were most likely formed by filamentous photosynthesizers. Other mat-associated biosignatures include silicified gas bubbles, domes and lenses that likely formed due to metabolic activity or the decay of buried organic matter. Some of these subsurface voids beneath the cohesive mats were inhabited by the earliest known forms of cavity-dwelling microbial communities that were probably dominated by chemotrophic or photosynthetic microbes. Recently discovered terrestrial microbial mats, once thriving in a fluvial-dominated setting, represent the oldest macroscopically-visible fossil traces of life on land, which is also supported by the occurrence of nearby paleosols that carry signals of biogenic sulfur fractionation.

The wealth of preserved microbial biosignatures from marine, fluvial, hydrothermal, and possibly planktonic settings combined with the high spatial and temporal resolution of the Barberton Greenstone Belt deposits is truly exceptional. Consequently, the BGB deserves an equal level of attention and protection for future generations like its Australian counterpart.

## 1. Introduction

The Archean rock record is sparse, largely metamorphosed, and preserved in fragmented Greenstone Belts, which occur wedged in between plutonic and metamorphic rocks in the cratonic lithosphere of nearly all continents. However, only the Barberton Greenstone Belt (BGB) of South Africa and Swaziland and the contemporaneous Pilbara Greenstone Belts (PGBs) of Western Australia contain well-preserved sedimentary rocks of Paleoproterozoic age ( $>3.2$  Ga), which experienced only greenschist facies metamorphism and relatively minor deformation. With an areal extent of  $\sim 6000$  km<sup>2</sup> and an age of  $\sim 3.55$ – $3.20$  Ga the BGB is significantly smaller and captures a slightly shorter time interval in comparison to the PGBs ( $\sim 60000$  km<sup>2</sup>,  $\sim 3.52$ – $2.94$  Ga), however, the deposits preserved in the BGB are characterized by often laterally consistent outcrops with correlatable facies, a generally better exposure, and very good accessibility. Lithified aquatic sediments in both of these volcano-sedimentary “enclaves” are considered the most suitable archive of ancient microbial life, as water is one of the fundamental requirements for life. Consequently, the sedimentary deposits have been extensively studied for traces of early life in these two localities and the reported findings have been critically reviewed especially for the Pilbara Greenstone Belts, where stromatolites, microfossils, and isotopic signals belong to the most dominant biosignatures (e.g. Allwood et al., 2006; Brasier et al., 2006; Wacey, 2009, 2012). The focus of this study here is to summarize and review the South African evidence of Paleoproterozoic life reported from the BGB, place them in a consistent stratigraphic framework, and discuss and evaluate the most recent findings.

## 2. Geology of the BGB

The Barberton Greenstone Belt of South Africa and Swaziland is located at the eastern margin of the Kaapvaal Craton and contains volcanic, shallow intrusive, and sedimentary rocks, ranging in age from  $<3.547$  to  $>3.219$  Ga (Byerly et al., 2019; Fig. 1). These age constraints are mainly derived from high-precision zircon U-Pb age dating of interbedded volcanic units and plutons surrounding the BGB, as well as detrital zircon geochronology. Rocks of the Barberton Supergroup (formerly named Swaziland Supergroup), are subdivided from base to top into three lithostratigraphic units: (1) the  $\sim 8$ – $10$  km thick, volcanic-dominated Onverwacht Group, which comprises the Komati, Hooggenoeg, Kromberg, and Mendon Formations (Viljoen and Viljoen, 1969; Anhaeusser, 1976; Lowe and Byerly, 2007; De Wit and Furnes, H., 2011); (2) the up to  $\sim 2$  km thick Fig Tree Group, predominantly composed of interlayered volcanoclastic strata that mark the final stages of major volcanism and the transition to deposition of terrigenous clastic units (Heinrichs and Reimer, 1977; Lowe, 1999a; Hofmann, 2005; Byerly et al., 2019); and (3) the up to  $3.5$  km thick, coarse-grained siliciclastic to conglomeritic Moodies Group, mainly derived

70 from the erosion of underlying units and uplifted plutonic rocks (Eriksson, 1977; Heubeck and Lowe,  
71 1994a, 1994b, 1999). The dominant large-scale orogeny of the BGB occurred contemporaneously with  
72 deposition of the Moodies Group at 3.225–3.215 Ga (Lamb and Paris, 1988; Heubeck et al., 2013).  
73 Although the BGB strata experienced several phases of major deformation during which they were folded,  
74 faulted and altered, the rocks are generally well-preserved in locally very thick and laterally-traceable  
75 sections (De Ronde and De Wit, 1994; Toulkeridis et al., 1998; Lowe and Byerly, 1999). A major fault  
76 system, the Inyoka Fault, transects the BGB approximately medially and divides it into a northern and  
77 southern facies, characterized by distinct differences in the preserved stratigraphy and depositional facies  
78 of especially the Onverwacht and Fig Tree Groups (Fig. 2). Although approximately coeval, these deposits  
79 represent previously geographically separated successions that are now in tectonic contact with another  
80 (Byerly et al., 2019). The greenstone belt fill can be further subdivided into several tectonostratigraphic  
81 blocks, each bordered by numerous, steeply dipping large and small faults (Lowe, 1999a; Lowe et al.,  
82 2012). Most rocks in the central part of the BGB experienced alteration temperatures of >300°C (Xie et  
83 al., 1997; Toulkeridis et al., 1998; Tice et al., 2004), however some primary mineralogy, textures, and  
84 sedimentary structures have been preserved in many units due to the combination of early silicification and  
85 the local partitioning of strain (Byerly et al., 2019).

86  
87

### 3. History of early life studies in the BGB

89 The BGB has a long history of studies focusing on traces of early life and the reconstruction of its habitat,  
90 metabolism, biogeochemical cycling, and mode of preservation (Table 1). Since the mid-1960s the  
91 occurrence of lenticular, spheroidal, and filamentous microstructures, interpreted as possible cellular  
92 microfossils, has been reported from carbonaceous cherts of the Onverwacht Group\* (Barghoorn and  
93 Schopf, 1966; Pflug, 1966, 1967; Schopf and Barghoorn, 1967; Pflug et al., 1969; Barghoorn, 1971). \*[Note  
94 that these samples were collected from the same outcrop, which was originally assigned to the Fig Tree  
95 Group, but later revised and changed to the upper Onverwacht Group (Pflug, 1967; Schopf, 1975; Lowe  
96 and Knauth, 1977).] In the following years simple spherical and filamentous microstructures have also  
97 been described from other Onverwacht Group cherts of the Mendon and Kromberg Formation (Engel et al.,  
98 1968; Nagy and Nagy, 1969; Brooks and Shaw, 1971; Brooks et al., 1973; Muir and Hall, 1974; Muir and  
99 Grant, 1976; Knoll and Barghoorn, 1977), however the exact stratigraphic position was often not clearly  
100 indicated, which made it challenging to put the individual findings in context to each other. In fact, the  
101 insufficient knowledge of the BGB stratigraphy at that time and the often poorly studied depositional facies,  
102 and paleoenvironmental context of the analyzed samples are central problems of most of these pioneering  
103 studies. Due to their often simply morphology and wide size range the biogenicity of almost all of the early-

104 reported microfossils has been questioned in several reviews (Schopf, 1975; Schopf and Walter, 1983;  
105 Altermann, 2001; Wacey, 2009), which suggested that except for the structures described by Muir and  
106 Grant (1976) and Knoll and Barghoorn (1977) all other findings should be treated as nonfossil artefacts,  
107 aggregates of amorphous carbonaceous matter or modern contaminants. More detailed sedimentological,  
108 geochronological, and tectonostratigraphic investigations of the BGB deposits (Lowe and Knauth, 1977;  
109 Kröner et al., 1991; Lowe and Byerly, 1999; Lowe et al., 2012), organic carbon isotope analysis (e.g. Oehler  
110 et al., 1972), the identification of possible stromatolites (de Wit et al., 1982; Byerly et al., 1986; Byerly and  
111 Palmer, 1991; Walsh, 2004), and new discoveries of mat-like laminations, lenticular, spheroidal, and  
112 filamentous microfossil in cherts of the Hooggenoeg, Kromberg, and Mendon Formations (Walsh and  
113 Lowe, 1985, 1999; Walsh, 1992; Westall et al., 2001; Glikson et al., 2008) supported previous findings  
114 (e.g. Pflug, 1966; Knoll and Barghoorn, 1977) and stimulated further investigations. In the following,  
115 carbonaceous laminations preserved in the shallow-water facies of the Buck Reef Chert (Kromberg  
116 Formation) have been studied in great detail and were interpreted as the remains of photosynthetic microbial  
117 mats (Tice and Lowe, 2004, 2006a, 2006b; Tice, 2009; Tice et al., 2011). Westall et al. (2006, 2011, 2015,  
118 2018) identified microbial biofilms and possible fossil bacteria in the Josefsdal Chert (Kromberg  
119 Formation) and suggested that these microbial communities were once thriving in a nearshore hydrothermal  
120 setting. Tubular, titanite-mineralized microstructures in basaltic pillow lava rims of the Hooggenoeg and  
121 Kromberg Formations were interpreted as being the result of microbial etching, and thus indicating the  
122 presence of submarine thermophilic microbial communities during basalt formation (Furnes, 2004;  
123 Banerjee et al., 2007; Furnes et al., 2007; Fliegel et al., 2010). However, the syngenicity and biogenicity of  
124 these putative oldest trace fossils has been strongly questioned and is currently still under debate  
125 (McLoughlin et al., 2012; Grosch and McLoughlin, 2014; Staudigel et al., 2015; Wacey et al., 2017;  
126 Hickman-Lewis et al., 2019 for a short review). More recently, the biogenicity of lenticular microfossils  
127 from the Kromberg Formation was further supported by *in situ* carbon isotope analysis (Oehler et al., 2017),  
128 while new findings of cell-like objects from the Buck Reef Chert were interpreted as degraded colonies of  
129 coccoidal bacteria (Kremer and Kaźmierczak, 2017). Moreover, Hickman-Lewis et al. (2018) reported  
130 carbonaceous laminations, resembling microbial biofilms and mats from the Middle Marker at the base of  
131 the Hooggenoeg Formation, making it to the most ancient claim for life in the BGB.  
132 In the last decade also the sand- and siltstones of Moodies Group (uppermost unit of the BGB), were  
133 carefully investigated for traces of early microbial life, which resulted in the discovery of large spheroidal  
134 microfossils (Javaux et al., 2010), widespread shallow-marine tufted microbial mats once formed by  
135 photosynthetic microorganisms (Noffke et al., 2006; Heubeck, 2009; Gamper et al., 2012; Homann et al.,  
136 2015) and remnants of cavity-dwelling microbial communities (Homann et al., 2016). Terrestrial microbial  
137 mats interbedded with fluvial sandstones and conglomerates, record a significant difference in their organic

138 carbon and nitrogen isotopes in comparison with the tidal marine mats and represent the oldest  
139 macroscopically-visible trace of life on land (Homann et al., 2018). The presence of a Paleoproterozoic  
140 terrestrial biosphere is further supported by the Moodies Group paleosols that carry signals of biogenic  
141 sulfur fractionation (Nabhan et al., 2016a, 2016b). In the following, a selection of the most promising and  
142 best documented claims for early life from the Onverwacht and Moodies Groups of the BGB will be  
143 described and discussed in more detail.

144

#### 145 **4. The 3.55–3.26 Onverwacht Group**

146 The Onverwacht Group consists of a up to 10 km thick succession of mostly of mafic and ultramafic  
147 volcanic rocks with minor felsic volcanic flow units and tuffs (Lowe and Byerly, 1999). Subordinate  
148 sedimentary units formed during episodic breaks in eruptive activity and have been widely silicified to  
149 bedded cherts, which host a large number of the reported traces of early life in the BGB, including microbial  
150 mats, microfossils, and possible stromatolites. Moreover, rare asteroid ejecta layers, composed of impact  
151 spherules, fine ash and dust, locally occur as discrete beds and record distal impact events of large asteroids  
152 with diameters ranging between 20–50 km (Fig. 2; Lowe and Byerly, 1986, 2018). The Onverwacht Group  
153 comprises four different formations (Komati, Hooggenoeg, Kromberg, and Mendon), which each can be  
154 further subdivided into informal members (e.g. H1 - H6). Within each member the cherts, which are capping  
155 individual volcanic units are designated with a "c" (e.g. H4c; Lowe and Byerly, 1999; Byerly et al., 2019).  
156 Overlying the basal Komati Formation, the 3.472 - 3.416 Ga Hooggenoeg Formation consists of thick  
157 sequence of tholeiitic basalts, minor komatiites, and thin chert units and can reach a thickness of up to 3900  
158 m on the western limb of the Onverwacht Anticline (Viljoen and Viljoen, 1969b, Lowe and Byerly, 1999).  
159 The 3.416 – 3.334 Ga Kromberg Formation on the west limb of the Onverwacht Anticline comprises an up  
160 to 1800-m-thick succession of black and banded chert (Buck Reef Chert, K1), mafic lapilli tuff and  
161 lapillistone (K2), and tholeiitic basalt (K3), while on the eastern limb of the anticline massive pillow basalt  
162 is more abundant. The top of the formation is marked by a regionally traceable chert unit, the Footbridge  
163 Chert (K3c; Viljoen and Viljoen, 1969, Lowe and Byerly, 1999). Conformably overlying the Kromberg  
164 Formation, the 3.334 – 3.258 Ga Mendon Formation has a thickness of >600m and records an alternation of  
165 volcanic cycles, each characterized by a komatiitic flow unit capped by a chert layer (Byerly, 1999).

166

#### 167 **4.1 Microbial mats**

168 The first systematic stratigraphic and petrographic analysis of all carbonaceous cherts in the Hooggenoeg,  
169 Kromberg, and Mendon Formation of the Onverwacht Group was made by Walsh (1992) and Walsh and  
170 Lowe (1999), who distinguished three main types: black-and-white banded, massive black, and black  
171 laminated chert. The carbonaceous matter in these cherts occurs mostly in the form of: fine laminations (1

172 – 20  $\mu\text{m}$  thick), carbonaceous wisps (10–50  $\mu\text{m}$  thick, 50–1000  $\mu\text{m}$  long) that are likely eroded fragments  
173 of the fine laminations, subrounded composite grains (100–1000  $\mu\text{m}$ ), and irregular-shaped simple grains  
174 (5–750  $\mu\text{m}$ ), and. Based on bulk  $\delta^{13}\text{C}_{\text{org}}$  values ranging between  $-40.8\%$  and  $-16.9\%$ , with a mean of  
175  $-29.8\%$  ( $n = 50$ ), Walsh and Lowe (1999) concluded that all the carbonaceous matter in the cherts is  
176 probably of biological origin, which was further supported by a detailed study of van Zuilen et al. (2007),  
177 combining Raman spectroscopy and SIMS (secondary ion mass spectrometry) analysis.  
178 In detail, the fine carbonaceous laminations that form layers of 0.5–2 cm thickness and occur predominantly  
179 in black-and-white banded cherts the Hooggenoeg (H2, H4c, H5c), Kromberg (K1, K3c), and Mendon  
180 Formation (M1c, M2c), were interpreted as remains of microbial mats (Walsh, 1992; Walsh and Lowe,  
181 1999; Trower and Lowe, 2016). The alternation of carbonaceous black bands with thin layers of pure  
182 (white) quartz in these cherts is likely comparable with alternating organic-rich and organic-poor sediments  
183 in modern microbial mats. The mats presumably formed in periods of volcanic quiescence but likely under  
184 the presence of hydrothermal activity. They are often interbedded with layers of composite carbonaceous  
185 grains, which Walsh (1992) compared to globular bacterial colonies or organic aggregates, however, the  
186 biogenicity of these grains still needs to be further established (Trower and Lowe, 2016). In the following,  
187 reported microbial mats and biofilms from the Middle Marker, the Buck Reef Chert, and Josefsdal Chert  
188 will be described in more detail.

#### 189 190 **4.1.1 Middle Marker**

191 The 3.472 Ga Middle Marker (H1) at the base of the Hooggenoeg Formation represents the oldest, relatively  
192 unmetamorphosed sedimentary unit of the BGB (Lanier and Lowe, 1982; Armstrong et al., 1990). It has a  
193 thickness of 3 to 6 m and is composed of silicified komatiitic ash and fine layers of relatively pure  
194 carbonaceous cherts that contain composite grains and carbonaceous wisps of proposed biogenic origin  
195 (Lanier and Lowe, 1982; Walsh, 1992; Lowe, 1999; Walsh and Lowe, 1999). Deposition occurred likely  
196 on a flat, tide- or wave influenced shelf in water depths of several 10s to 100 m (Byerly et al., 2019).  
197 Fine, crinkly laminations, interbedded with the volcanoclastic sand- and siltstones of this unit, have been  
198 interpreted as fossil microbial mats by Hickman-Lewis et al. (2018), mainly based on their carbonaceous  
199 composition, micro-tufted morphology, sediment trapping and cohesive behavior, and the occurrence of  
200 wisp-like structures, interpreted as erosional mat (Fig. 3A and B). The carbonaceous laminations occur in  
201 packets of 200  $\mu\text{m}$  to 2.5 mm thickness, contain detrital quartz and volcanic grains, and generally have a  
202 low surficial relief, which is described by the authors as micro-tufted (Fig. 3A and B). These crinkly, micro-  
203 tufted structures ( $<100\mu\text{m}$  in height) of proposed primary biogenic origin can be distinguished from pseudo-  
204 tufted structures (up to 0.8 mm in height) that formed secondary as a result of plastic deformation triggered  
205 by the settling of dense particles (Fig. 3C and D; Hickman-Lewis et al., 2018). The micro-tufted structures

206 were further used by Hickman-Lewis et al., (2018) to tenta  
207 were formed by anoxygenic phototrophs. However, it is hard to constrain the microbial metabolism relying  
208 on mat morphology alone, especially if it is only of minor topographic relief and secondary deformation  
209 structures are present. More valuable insights into the metabolism(s) of the Middle Marker mats could be  
210 gained from the analysis of organic carbon isotopes, which would also help to further strengthen their  
211 biogenicity.

212

#### 213 **4.1.2 Buck Reef Chert**

214 The 3.416 Ga Buck Reef Chert (K1) is a 250–400-m-thick unit of carbonaceous and ferruginous cherts at  
215 the base of the Kromberg Formation, exposed continuously along nearly 50 km of strike in the west limb  
216 of the Onverwacht Anticline (Kröner et al., 1991; Lowe and Worrell, 1999). A correlative section in the  
217 east limb of the Onverwacht Anticline comprises three 10–25-m-thick chert units (Kc1, Kc2, Kc3), that are  
218 interbedded with basalt flows (Walsh, 1992; Lowe and Byerly, 1999). The cherts are thought to be of  
219 primary origin and likely precipitated from normal marine water, which was saturated with respect to  
220 amorphous silica during the Archean (Lowe, 1999b; Knauth and Lowe, 2003; Tice and Lowe, 2006a) rather  
221 than from hydrothermal fluids (de Wit et al., 1982; Westall et al., 2001). Sediments of the Buck Reef Chert  
222 were deposited on subsiding open-marine volcanic platform and can be subdivided in three main  
223 depositional facies (basal evaporitic, middle platform, and deep basin), which reflect deposition under  
224 successively deeper-water conditions (Tice and Lowe, 2004). The silicified evaporites from the evaporitic  
225 facies, were originally interpreted as remnants of nahcolite (Lowe and Worrell, 1999) but may represent  
226 pseudomorphs after aragonite (Otálora et al., 2018). Fine anastomosing carbonaceous laminations (Fig. 4A-  
227 F) and in places ripped up, plastically deformed rolled-up fragments (Fig. 5 A and B), occurring within  
228 black bands in black-and-white banded cherts of the platform facies, were interpreted as remnants of  
229 cohesive microbial mats (Walsh and Lowe, 1999; Tice and Lowe, 2004, 2006a, 2006b; Tice, 2009; Tice et  
230 al., 2011). The mats were once thriving in shallow-water, photic zone paleoenvironments below fair-  
231 weather wave base and show three distinct mat morphotypes: (1) alpha-type, fine carbonaceous laminations  
232 that incorporate and loosely drape detrital grains underlying detrital grains and form silica-filled lenses (Fig.  
233 4A and B); (2) beta-type, fine meshworks of filament-like strands (<5µm in diameter), which drape  
234 underlying detrital grains (Fig. 4C and D); and (3) gamma-type, evenly spaced flat laminations that tightly  
235 drape underlying sediments (Fig. 4E and F; Tice, 2009). The formation of different mat morphotypes is  
236 thought to be primarily controlled by local variations in ambient light intensity and/or current energy.  
237 Consequently, the first two morphotypes (alpha and beta) probably formed in shallower water, which is  
238 also supported by their more complex morphology and association with coarser-grained sediments (Tice  
239 2009). Bulk organic carbon isotope measurements of the carbonaceous laminations, with  $\delta^{13}\text{C}_{\text{org}}$  values

240 ranging between  $-36.9\%$  and  $-20.1\%$ , and a mean of  $-29.9\%$  ( $n = 19$ , Tice and Lowe 2006b), serve as  
241 additional evidence for a biogenic origin of the mats, which were formed by photosynthetic microbes that  
242 most likely applied hydrogen-based carbon fixation (Tice and Lowe, 2004a, 2006a). Raman  
243 microspectroscopic analysis further revealed that the carbonaceous matter preserved in the Buck Reef Chert  
244 has experienced sub- to lower-greenschist facies temperatures, consistent with regional peak metamorphic  
245 temperatures, and thus confirming its syngenetic origin (Tice et al., 2004; van Zuilen et al., 2007). Overall,  
246 the microbial mats preserved in the Buck Reef Chert represent one of the best documented evidence for  
247 ancient life in the Onverwacht Group. Future work could focus more on micro-scale investigations, increase  
248 the spatial resolution of organic carbon isotope measurements, and try to acquire also nitrogen isotope  
249 values in order to learn more about the biogeochemical cycling of these elements by the mat-forming  
250 microbial communities.

251  
252

### 253 **4.1.3 Josefsdal Chert**

254 The Josefsdal Chert comprises a 6–30-m-thick succession of silicified volcanoclastic rocks, located in a  
255 fault-bounded sliver, and is considered to be the lateral equivalent of the 3.334 Ga Footbridge Chert (K3c;  
256 (Kröner et al., 1996; Lowe and Byerly, 1999) at the top of the Kromberg Formation (Hofmann and Bolhar,  
257 2007; Westall et al., 2015). Sedimentary structures, such as ripple marks, planar- and cross-lamination  
258 indicate that deposition likely occurred in tidal, nearshore environments under the influence of  
259 hydrothermal activity, which is supported by REE patterns with positive Eu and Y anomalies and was likely  
260 driven by the circulation of silica-saturated seawater through cooling basaltic lavas that occur  
261 stratigraphically below the Josefsdal Chert (Hofmann and Harris, 2008; Westall et al., 2011, 2015, 2018).  
262 Cracks, only a few  $\mu\text{m}$  in width, occurring in structures interpreted as fossil biofilms from these deposits,  
263 were further used to infer periods of subaerial exposure, desiccation, and evaporation (Westall et al., 2001;  
264 2006). Such cracks are, however, less suitable to reconstruct the depositional context, as they are only  
265 visible with the SEM (scanning electron microscope) and not in the outcrops. Altermann (2001) suggested  
266 that these cracks and the pseudomorphic evaporite minerals, as well as some putative rod-shaped  
267 microfossils (2–3.8 mm long and interpreted as remnants of sulphate-reducing bacteria) described by  
268 Westall et al. (2001, 2006) from these cherts, might represent sample preparation artefacts introduced  
269 during HF etching (Wacey, 2009). Moreover, the fact that the anions of the putative, often idiomorphic,  
270 evaporite crystals have been replaced by fluorine (Westall et al., 2006) further indicates that they could  
271 represent artefacts, especially as it has been shown that mineral artefacts such as fluorides and fluosilicates  
272 commonly form during HF etching (Karkhanis, 1977) and might mimic evaporitic minerals. A more  
273 promising candidate for life in these deposits are therefore the structures that are visible in petrographic

274 thin section and resemble silicified biofilms and microbial mats (Fig 6 A-C). The microbial mat-like  
275 structures occur in banded black and white cherts as layered packets, 100–1000  $\mu\text{m}$  thick, that are composed  
276 of  $\sim 10\mu\text{m}$  thin, wavy carbonaceous biofilms with incorporated fine-grained detrital volcanic clasts and  
277 quartz grains (Westall et al., 2006; 2011; 2015). Torn and plastically deformed fragments of these biofilms  
278 occur partially peeled of below and above distinct mat horizons, which is interpreted as evidence for  
279 contemporaneous (lateral?) injection of hydrothermal fluids (Fig. 6D, Westall et al., 2015). A single biofilm  
280 (1–4  $\mu\text{m}$  thick) exposed on fresh fractured bedding surface has been extensively studied by Westall et al.  
281 (2001, 2006, 2011; sample 96SA05) and SEM observations revealed the presence of multiple layers of  
282 parallel filament-like structures with constant diameter of 0.25  $\mu\text{m}$ , which are embedded in a granular to  
283 smooth film interpreted as extracellular polymeric substance. Carbonaceous clots, 50–500  $\mu\text{m}$  in diameter  
284 and interpreted as degraded remnants of chemosynthetic biomass, represent another proposed biosignature  
285 from Josefsdal Chert (Westall et al., 2015), however their biogenicity still needs to be further established.  
286 Two bulk organic carbon isotope measurements from the Josefsdal Chert show  $\delta^{13}\text{C}_{\text{org}}$  values of  $-22.7\text{‰}$   
287 (bulk sample, Westall, et al 2001) and  $-26.8\text{‰}$  (carbon-rich black layer, Westall et al., 2006). While *in situ*  
288 measurements of the carbonaceous biofilms yield  $\delta^{13}\text{C}_{\text{org}}$  values of  $-45\text{‰}$  to  $-13\text{‰}$  and a single  $\delta^{34}\text{S}$  value  
289 of  $-24\text{‰}$  (Westall et al., 2015). These values support a biogenic origin of the biofilms/mats and were further  
290 used to conclude that the latter were formed by anoxygenic photosynthesizers and sulphur reducing bacteria  
291 (Westall et al. 2011, 2015). Future *in situ* isotope studies on the organic remains in these samples should  
292 increase the amount of data points and aim to better document the analytical areas (see e.g. Williford et al.  
293 2013, 2016) in order to spatially resolve the large range of  $\delta^{13}\text{C}_{\text{org}}$  values, and to distinguish it from the  
294 background signal of the carbonaceous cherts, which might differ significantly, as documented by Oehler  
295 et al. (2017) for samples of the Buck Reef Chert that show  $\delta^{13}\text{C}_{\text{org}}$  values ranging between  $-47.1\text{‰}$  and  
296  $-24.0\text{‰}$ .

#### 4.2 Microfossils

299 The positive identification of Archean microfossils is due to their often very simple morphology extremely  
300 challenging, several well-established criteria exist (see Schopf, 2004; Brasier et al., 2006; Wacey, 2009),  
301 while *in situ* carbon isotope analysis of individual microfossil candidates has become another required  
302 method for the evaluation of their biogenicity in recent years (e.g. House et al., 2013; Lepot et al., 2013;  
303 Williford et al., 2013, 2016). Putative microfossils in the carbonaceous cherts of the Onverwacht Group are  
304 extremely rare. The first systematic analysis of Walsh (1992) and Walsh and Lowe (1999) revealed that  
305 only 9 of more than 400 analyzed samples contained possible microfossils of filamentous, lenticular, and  
306 spheroidal shapes.

308 **4.2.1 Filamentous structures**

309 Filamentous microstructures of carbonaceous composition were identified in a single 2 cm thick black-and-  
310 white banded chert layer in the upper Hooggenoeg Formation (Walsh and Lowe, 1985; Walsh 1992). These  
311 tread-like or cylindrical, unbranched filaments are solid, 0.2 – 2.5  $\mu\text{m}$  in diameter, up to 200  $\mu\text{m}$  long and  
312 occur associated with carbonaceous laminations interpreted as microbial mats. Although originally  
313 classified as possible microfossils Walsh (2000) noted that they may have formed abiotically and could  
314 thus represent simple mineral filaments (Wacey, 2009).  
315 More convincingly biological filaments occur associated with fossil mats in several localities of the Buck  
316 Reef Chert (K1 and K1c2; Byerly et al., 2019). The hollow cylindrical filaments, 1.2 – 1.4  $\mu\text{m}$  in diameter  
317 and 10 – 150  $\mu\text{m}$  in length, are composed of carbonaceous matter and fine pyrite (Fig. 7A-C). They mostly  
318 occur oriented subparallel to bedding or sometimes as interwoven, tangled clumps (Walsh and Lowe, 1985;  
319 Walsh 1992). These hollow, sheath-like filaments are similar in size and shape to modern filamentous  
320 bacteria and are of possible organic origin (Walsh 1992, Altermann, 2001), however, high-resolution  
321 petrographic and detailed *in situ* carbon isotope analysis would be desirable to further support this  
322 interpretation.

323  
324

325 **4.2.2 Lenticular structures**

326 Lenticular structures (previously named “spindle-shaped” structures) represent a group of enigmatic  
327 microfossils that are also well-known from the Pilbara Craton of Western Australia where their biogenicity  
328 is well established (e.g. Sugitani et al., 2007, 2010, 2013, Oehler et al., 2009, 2017; House et al., 2013;  
329 Kozawa et al., 2018). There, the lenticular objects occur individually or in groups or chains of several  
330 individuals. Lense- or, disk-shaped microstructures, 30–60  $\mu\text{m}$  in long axis, with hollow centers and  
331 carbonaceous walls have been first documented in the BGB by Pflug (1966, 1967) and Pflug et al., (1969)  
332 from cherts of the Fig Tree Group that were later assigned to the upper Onverwacht Group (Mendon  
333 Formation, previously named Swartkoppie Formation, (Schopf, 1975; Lowe and Knauth, 1977)). The  
334 structures gently taper towards the ends of their long axes, occur isolated or sometimes in groups of two or  
335 more specimens (Fig. 8A-D), which are connected at their poles, and were interpreted as the remains of  
336 thread-like bacterial colonies (Pflug, 1966, 1967). Walsh (1992) interpreted very similar lenticular  
337 structures, 13–135  $\mu\text{m}$  long and 4.5–61  $\mu\text{m}$  wide, from detrital layers above the basal evaporitic facies of  
338 the Buck Reef Chert (K1) as possible sheaths of colonies of bacterial cells or carbonaceous coatings around  
339 former gypsum crystals (Fig. 8E-H). A biological origin of the structures is supported by *in situ*  $\delta^{13}\text{C}_{\text{org}}$   
340 analysis that revealed values ranging between -39.3‰ to - 35.5 ‰, consistent with autotrophic carbon  
341 fixation (n = 8; Oehler et al., 2017). Based on their robust morphology, shallow water habitat and  $\delta^{13}\text{C}_{\text{org}}$

342 values Oehler et al. (2017) proposed that the lenticular forms might represent microbes with a planktonic  
343 stage in their life cycle, making it to a very promising claim for microbial life in the BGB.

344

### 345 **4.2.3 Spheroidal structures**

346 Spheroidal microstructures of carbonaceous composition belong to a very common group of putative  
347 microfossils in the Onverwacht Group but the evaluation of their biogenicity is due to their simple  
348 morphology often very challenging.

349 Glikson et al. (2008) identified clusters of spheroidal, cell-like objects (2–10  $\mu\text{m}$  in diameter) with granular  
350 walls from cherts of the Hooggenoeg Formation (H3c and H5c), which display features of possible cell  
351 wall degradation (Fig. 9A and B). The spheroids are comparable with the modern hyperthermophilic  
352 *Methanocaldococcus jannaschii* and were thus interpreted as remnants of chemosynthetic microbes once  
353 thriving in a seafloor hydrothermal system. This is a promising sign for life, but follow-up studies should  
354 also document the sedimentological context, perform analysis on more than two samples, and include *in*  
355 *situ* isotope measurements (Wacey et al., 2009). Large granular-walled spheroids and ellipsoids (10–84  $\mu\text{m}$   
356 in length; Fig. 9C and D) and clusters of thin-walled spheroids (4.5–12.8  $\mu\text{m}$  in diameter; Fig. 9E and F)  
357 from the Buck Reef Chert were interpreted as probable microfossils of coccoidal bacteria or spores (Walsh,  
358 1992). However, these simple spheres may be produced abiotically in various ways and were therefore  
359 reinterpreted as abiotic self-organized structures, such as spherulitic chert (Brasier et al., 2006). Kremer  
360 and Kazmierczak (2017) reported spheroidal microstructures, 3–12  $\mu\text{m}$  in diameter, from the Buck Reef  
361 Chert (K1c2) and tentatively conclude that they may represent the variably degraded remains of coccoidal  
362 cyanobacteria (Fig. 9G and H). Although the cell-like objects occur in groups or clusters, preserved in black  
363 cherts with bulk  $\delta^{13}\text{C}_{\text{org}}$  values of  $-26.5\text{‰}$  and  $-24.3\text{‰}$  ( $n = 2$ ), their outer walls often have a more angular  
364 than rounded appearance, which resemble crystal terminations, thus making a biological origin less  
365 favorable (Hickman-Lewis, 2019). Alternatively, these objects might represent carbonaceous linings on  
366 replaced minerals or crystal rims (Brasier et al., 2006). Moreover, beyond morphological similarity, the  
367 positive identification of cyanobacteria and oxygenic photosynthesis hundreds of millions of years before  
368 most other evidence, requires independent geochemical evidence for the local presence of free oxygen,  
369 which is currently not available. Future studies should include nanoscale analysis of the putative cell walls  
370 and *in situ* isotope measurements.

371 Another occurrence of possible organic microspheres, 1– 4  $\mu\text{m}$  in diameter, has been described by Knoll  
372 and Barghoorn (1977) from the Msauli Chert (M1c; Mendon Formation, previously named Swartkoppie  
373 Formation (Lowe, 1999c)), which was deposited in shallow-water nearshore environments (Fig. 9I). These  
374 carbonaceous spheres occur as isolated or paired objects, are often flatten, wrinkled or folded, show a  
375 narrow unimodal size frequency distribution ( $n = 200$ ), evidence of possible cell division, and were

376 interpreted as the remains of primitive prokaryotes (Knoll and Barghoorn, 1977). However, without any  
377 geochemical analysis also these structures cannot be unambiguously identified as biological (Wacey, 2009).

378

379

### 380 **4.3 Stromatolites**

381 Compared to its Australian counterpart the currently known stromatolite occurrences in the BGB are very  
382 rare. Byerly et al. (1986) reported putative pseudocolumnar stromatolites that crop out for more than 10 km  
383 along strike in grey to black cherts assigned to member M2c of the ~3.23 Ga Mendon Formation (Walsh,  
384 2004; Lowe and Byerly, 2015), which is interbedded with komatiitic lava flow deposits. [Note that these  
385 outcrops were initially assigned to the Fig Tree Group (Byerly et al., 1986), but are now thought to belong  
386 to the Mendon Formation in the upper Onverwacht Group (Lowe, 1994)]. The possible stromatolites occur  
387 in layers of <1 to 20 cm thickness and display variable morphologies, ranging between low-relief,  
388 asymmetrical, sometimes laterally-linked domes (1–3 cm wide and 0.5–3 cm high), rare pseudocolumns  
389 with bridging laminae (up to 10 cm height), and crinkly stratiform laminations (50–100 μm thick; Fig. 10A  
390 and B). Individual laminae are composed of minor amounts of primary carbonaceous matter and variable  
391 amounts of secondary, fine-grained, often idiomorphic tourmaline minerals (sometimes up to 50%), which  
392 may have been derived through the hydrothermal remobilization of previously formed, boron-rich  
393 evaporites (Fig. 10C; Byerly and Palmer, 1991). Alternatively, the tourmaline mineralization could have  
394 been caused by heating and partial ocean evaporation related to a large asteroid impact recorded by spherule  
395 beds S5 and S8, which occur associated with some of the stromatolites (Lowe and Byerly, 2015).  
396 Conglomerates composed of laminated silica chips occur in the throughs between stromatolite domes and  
397 have been interpreted as fragments of eroded stromatolites or sinter crusts, likely deposited in the aftermath  
398 of a large impact (Fig. 10D). Similar stromatolite-crust chip conglomerates have also been reported from  
399 the Fig Tree Group (Sheba Formation) where they are overlain by spherule bed S5 (Lowe and Byerly, 2015,  
400 2018). The stromatolitic structures were possibly formed by hyperthermophilic microbial communities in  
401 shallow-water depositional environments during periods of relative volcanic quiescence and likely  
402 experienced the profound effect of distant asteroid impacts (Byerly et al., 1986; Lowe and Byerly, 2018).  
403 The widespread occurrence, morphological variability, and similarity to other fossil and modern  
404 stromatolites suggest a biogenic origin of these structures (Awramik, 1992). However, organic carbon  
405 isotope measurements, three-dimensional morphological investigations, a better documentation of the  
406 different morphotypes (Allwood et al., 2006), combined with high-resolution petrographic analysis, and a  
407 clear distinction from possibly abiogenic hot-spring silica crust precipitates (Lowe, 1994) would be  
408 desirable to further support this interpretation.

## 5. The ~3.22 Ga Moodies Group

The ca. 3.22 Ga Moodies Group is the uppermost stratigraphic unit of the BGB and represents the world's oldest well-preserved alluvial to shallow-marine tidal deposit. It consists of a up to 3.5 km thick succession of quartz-rich sandstones with subordinate conglomerates, mudstones, siltstones, thin volcanic tuff beds, minor banded iron formations and a basaltic lava, deposited in marine (deltaic, inter-, and subtidal) and terrestrial (alluvial, fluvial, possibly aeolian) paleoenvironments (Hall, 1918; Visser, 1956; Anhaeusser, 1976; Eriksson, 1977, 1979, Heubeck and Lowe, 1994a, 1999; Simpson et al., 2012; Homann et al., 2015, 2018; Heubeck et al., 2016). The age of the Moodies Group is tightly constrained by Uranium–lead dating of single-zircons from several dacitic tuffs and rare felsic dykes, which indicate that deposition began about  $3.223 \pm 1$  Ga and had ended by about  $3.219 \pm 9$  Ga (De Ronde and Kamo, 2000; Heubeck et al., 2013). Moodies strata north of the Inyoka Fault are preserved in several, commonly northward-overturned synclines that are tectonically separated by major faults (Fig. 2). These deposits not only contain a large variety of well- preserved sedimentary structures, they also offer a high-resolution archive of Paleoproterozoic surface and sedimentation processes, as well as a unique window into a widespread, diverse and well adapted microbial ecosystem. Reported biosignatures from the Moodies Group include intertidal and fluvial microbial mats, silicified remnants of cavity-dwelling microorganisms (coelobionts), and large organic-walled microfossils (acritarchs), as detailed below.

### 5.1 Microbial mats

Fossil microbial mats in the Moodies Group have been identified so far in intertidal deposits of the Saddleback Syncline and in alluvial-fluvial deposits of the Dycedale Syncline (Fig. 11A-C). In the Saddleback Syncline the mats are preserved as carbonaceous, crinkly laminations (0.5–1 mm thick), interbedded with medium- to coarse-grained sandstones, and associated with desiccation cracks (Fig. 12A) They represent the oldest known examples of siliciclastic tidal mats in the geological record (Noffke et al., 2006; Heubeck, 2009; Gamper et al., 2012; Homann et al., 2015). These mats draped and stabilized horizontally laminated and rippled sandstones, and show an enrichment in fine-grained quartz and feldspar, as well as heavy mineral grains (zircon and rutile or anatase), likely caused by microbial baffling and trapping, which is a commonly observed in epibenthic microbial mats (Gerdes et al., 2000). Microbial-mat-associated structures such as eroded mat fragments (mat chips), macroscopic tufts, shrinkage cracks, silicified gas domes and lenses, and subvertical fluid-escape structures are indicative for a former cohesive consistency and very common features in these deposits supporting the biogenic origin of the mats (Fig. 12B-D; Heubeck, 2009; Homann et al., 2015, 2016, 2018), while microbial wrinkle structures previously reported by Noffke et al. (2006) have not been observed in any of the follow-up studies. A detailed study

784

444 of the sedimentological and paleoenvironmental context of these fossil mats revealed that they are laterally  
445 traceable for ~15 km in a ~1000 m-thick succession in the lower part of the Saddleback Syncline and show  
446 distinct morphological adaptations to different hydrodynamic settings: (1) planar-type in coastal floodplain,  
447 (2) wavy-type in intertidal, and (3) tufted-type in upper inter- to supratidal facies (Homann et al., 2015).  
448 Such facies dependent changes in the prevalent mat morphotypes are to be expected in a dynamic, tidally-  
449 influenced coastal environment and serve as an additional biogenicity indicator (Allwood et al., 2006;  
450 Brasier et al., 2006). Moreover, the widespread occurrence of these fossil mats is consistent with a primary,  
451 microbially mediated, cohesive erosion-resistant relief on the paleosurface that was locally deformed by  
452 migrating gases and fluids, and in places eroded and incorporated in mat-chip conglomerates.  
453 Based on the restriction of the mats to shallow-water, photic zone environments and their apparent absence  
454 in subtidal settings, it is very likely that they were formed by phototrophic microbial communities (Noffke  
455 et al., 2006; Heubeck, 2009, Homann et al., 2015). In fact, the Moodies microbial mats show some striking  
456 morphological similarities to modern cyanobacterial mats e.g. from Bahar Alouane, Tunisia (Fig. 12A-D;  
457 Gerdes et al., 2000; Gerdes, 2007), Shark Bay, Australia (Jahnert and Collins, 2013), 2013), Texas Gulf  
458 Coast, USA (Bose and Chafetz, 2009), and the Red Sea of Saudi Arabia (Taj et al., 2014). Especially the  
459 occurrence of mats with macroscopic, 0.3-to-1 cm-high tufts that closely resemble tufted mats build by  
460 filamentous cyanobacteria (Fig. 12C), led to the conclusion that the tufted mats of the Moodies Group were  
461 perhaps build by ancestral cyanobacteria (Homann et al., 2015). Even tough, no geochemical data  
462 supporting the local presence of free oxygen (and thus oxygenic photosynthesis) at 3.22 Ga have been found  
463 so far in the Moodies Group, fossil evidence indicative for ancient gas production, accumulation, and  
464 migration is plentiful in the near vicinity of the mats. Now chert-filled cavities in the interior of some tufts  
465 likely represent silicified gas bubbles that were trapped within the mat fabric, which is a common feature  
466 in cyanobacterial mats that produce oxygen-rich bubbles with strikingly similar morphologies (Fig. 12C;  
467 Bosak et al., 2010; Homann et al., 2015). Other types of silicified cavities include domes and bedding  
468 parallel lenses beneath the fossil mats that either formed through accumulation of gases produced by  
469 metabolic activity, due to the decay of organic matter, or alternatively by tidal-driven hydraulic pumping  
470 of the ambient air trapped in pore space (Figs. 12D and 14; Homann et al., 2016). Some of these cavities  
471 where also inhabited by microbial communities (see below in 5.2).  
472 Besides the main mat occurrence in the tidal marine deposits of the Saddleback Syncline, fossil microbial  
473 mats also have been identified in the Dycedale Syncline (Homann et al., 2018), where a large variety of  
474 sedimentary structures indicates that this succession records a transition from alluvial-fluvial (terrestrial) to  
475 tide-influenced marine sedimentation (Heubeck and Lowe, 1994; Eriksson et al., 2006; Heubeck et al.,  
476 2016). These terrestrial mats occur confined to fluvial deposits at the base of a transgressive sequence that  
477 gradually deepens upward through deltaic, and medium-energy tidal, into subtidal siliciclastic deposits.

478 They are interbedded with gravely sandstones, drape conglomerate beds, are plastically deformed by 10-  
479 to 50-cm-high fluid-escape structures, and commonly experienced periods of subaerial exposure and  
480 desiccation evidenced by associated desiccation cracks (Fig. 13A and B). The terrestrial microbial mats of  
481 the Dycedale Syncline currently represent the oldest direct fossil trace for life on land (Homann et al.,  
482 2018). Overgrowth rims in pyrites from Moodies Group paleosols show signs of biogenic sulfur  
483 fractionation ( $\delta^{34}\text{S}_{\text{VCDT}}$  values between  $-20\%$  and  $-24.5\%$ ) and provide additional geochemical evidence  
484 for the presence of a Paleoarchean terrestrial biosphere (Nabhan et al., 2016a, b). Compared to the marine  
485 mats the carbonaceous laminae of terrestrial mats are similarly well preserved, but with up to 4 mm of  
486 preserved thickness often thicker than their marine counterparts (Fig. 11A and B; Fig. 13C). They are  
487 composed of a dense meshwork of interwoven filament-like microstructures that envelop fine-grained  
488 detrital particles whose long axes are preferentially aligned parallel to bedding (Fig. 13D and E; Homann  
489 et al., 2018). Individual carbonaceous filamentous structures are 1–3  $\mu\text{m}$  in diameter and resemble modern  
490 biofilm-forming, filamentous microorganisms. In places, a notable enrichment of tourmaline minerals can  
491 be observed in the mat fabric, which has also been reported from the stromatolitic laminae of the Mendon  
492 Formation (Byerly et al., 1986; Byerly and Palmer, 1991) and might be driven by evaporitic processes, but  
493 certainly demands further investigations. Raman spectroscopic analyses confirmed that both the terrestrial  
494 and marine mats are composed of organic carbon that has experienced similar peak temperatures of  $\sim 365^\circ\text{C}$ ,  
495 consistent with the metamorphic grade of the Moodies Group (Xie et al., 1997; Tice et al., 2004) and thus  
496 demonstrating their synsedimentary origin and biogenicity (Homann et al., 2018). A detailed study of  
497 Homann et al. (2018) documented a significant difference in the biogeochemical cycling of carbon and  
498 nitrogen in terrestrial and marine mats. The preserved organic matter in the terrestrial mats shows  $\delta^{13}\text{C}_{\text{org}}$   
499 values ranging between  $-23.6\%$  and  $-17.9\%$  (mean =  $-21.2\%$ ;  $n = 36$ ) and  $\delta^{15}\text{N}$  values between  $+1.9\%$   
500 and  $+5.6\%$  (mean =  $+4.3\%$ ;  $n = 10$ ), in contrast to marine mats that show  $\delta^{13}\text{C}_{\text{org}}$  values ranging between  
501  $-33.9\%$  and  $-21.3\%$  (mean =  $-27.4\%$ ;  $n = 30$ ) and  $\delta^{15}\text{N}$  values between  $-0.7\%$  and  $+3.1\%$  (mean =  
502  $+1.8\%$ ;  $n = 10$ ). This  $\delta^{13}\text{C}_{\text{org}}$  composition of the terrestrial mats is consistent with autotrophic carbon  
503 fixation through the Calvin–Benson cycle, while  $\delta^{13}\text{C}_{\text{org}}$  values of the marine mats are best explained by  
504 carbon fixation via the Wood–Ljungdahl pathway, which includes acetogenic bacteria, methanogens and  
505 sulfate reducers. The observed trend in the Moodies Group microbial mats with  $\delta^{15}\text{N}$  values from as low as  
506  $-1\%$  (marine) to up to  $+5\%$  (terrestrial) likely reflects increasing fixed-nitrogen (i.e., nitrate, nitrite or  
507 ammonium) and conversion to  $\text{N}_2\text{O}/\text{N}_2$  in the terrestrial habitats, which further suggests that they possessed  
508 a fundamentally different respiratory community at depth in the mat, one that must have been sufficiently  
509 oxygenated for aerobic Nitrogen cycling (Ader et al., 2016; Stüeken et al., 2016). Alternatively, the  
510 contrasting nitrogen isotope compositions between terrestrial and marine settings could be related to a

511 constant flux of atmospherically-fixed nitrogen on the early land surface that was probably too diffuse to  
512 be a significant source of fixed nitrogen to the marine biosphere (Homann et al., 2018).

513

## 514 **5.2 Cavity-dwelling life**

515 Lens-shaped, laterally tapering cavities, up to tens of centimeters in width and <0.5 cm in height, frequently  
516 occur beneath fossil microbial mat in intertidal deposits of the Saddleback Syncline (Fig. 14A; Homann et  
517 al., 2016). The silicified cavities resemble gas-filled, fenestral hollows in modern coastal environments that  
518 commonly form beneath cohesive, impermeable microbial mats and mat-bound sediments (Gerdes et al.,  
519 2000; Schieber et al., 2007). Due to the presence of carbonaceous laminations and wisps these chert lenses  
520 were initially interpreted as partially silicified epibenthic microstromatolites or thick mucilaginous mats  
521 (Heubeck 2009; Gamper et al., 2011), however, Homann et al. (2016) reported the additional presence of  
522 pendant columnar microstromatolites attached to the ceilings of former cavities and concluded that they  
523 must have accreted downwards in an open void space of syndimentary origin (Fig. 14B-E). This gravity-  
524 oriented geometry and the downward-accretionary growth habit is well known from cavity-dwelling  
525 microorganisms (coelobionts; Kobluk and James, 1979; Jakubowicz et al., 2014), which have also been  
526 reported from syndimentary cavities beneath microbial mats in sandstones of the Neoproterozoic Fortescue  
527 Group in Australia (Rasmussen et al., 2009). In places, sub-circular to ovoid-shaped fenestrae (~500 µm in  
528 diameter) that resemble trapped gas bubbles occur wedged between the carbonaceous laminae (Fig. 14C).  
529 SEM observations of the cavity-filling cherts reveal the presence of: (1) polygonal structures after HF  
530 etching for 28 days, interpreted as remnants of extracellular polymeric substance (EPS, Gamper et al.,  
531 2012), and (2) a meshwork of interwoven filamentous molds of likely biogenic origin that is completely  
532 embedded in the chert (Fig. 14F; unetched samples, Homann et al., 2016). The non-branching filaments  
533 (0.3–0.5 µm in diameter, n = 180) display a subdivision in regularly spaced, ~2-µm- long, rod-shaped  
534 segments and have a tubular morphology in cross section (Fig. 14G and H). Bulk carbon isotope  
535 measurements of the chert-bearing sandstones show  $\delta^{13}\text{C}_{\text{org}}$  values between -23.8‰ and -14.1‰ (mean =  
536 -20.5‰, n = 15; Gamper et al., 2012), however, *in situ* measurements of the carbonaceous laminae within  
537 the chert-cemented cavities yield  $\delta^{13}\text{C}_{\text{org}}$  values ranging between -32.3‰ and -21.3‰ (mean = -26.5‰; n  
538 = 12) that are probably more representative. These values are consistent with a purely chemotrophic or a  
539 photosynthetic community of coelobionts and support the biogenicity of the oldest evidence for cavity-  
540 dwelling life on Earth (Homann et al., 2016). Moreover, these findings support the view the cavities were  
541 among the first ecological niches to have been occupied by early microbial communities.

545 Carbonaceous spheroidal microstructures, 31–300  $\mu\text{m}$  in diameter (mean=122  $\mu\text{m}$ , n=98), have been  
546 identified in bedded siltstones and shales from underground drill cores that were assigned to the Clutha  
547 Formation and drilled 600m below the surface in the Agnes gold mine, Moodies Hills Block (Javaux et al.,  
548 2010). The carbonaceous structures are visible in petrographic thin sections and resistant to extraction via  
549 acid maceration (Fig. 15A-D). They show wrinkled and folded textures, a ~160-nm-thick wall with a  
550 homogenous ultrastructure and were interpreted as flattened, hollow, and partially degraded, organic-walled  
551 vesicles with preserved cell lumen (Fig. 15E-F; Javaux et al., 2010). Bulk carbon isotopes measurements  
552 show a large spread in  $\delta^{13}\text{C}_{\text{org}}$  values ranging between -16.4% and -28.3%, with an average of -22.4%  
553 (n=22), but no difference in the  $\delta^{13}\text{C}_{\text{org}}$  values between samples with and without microfossils has been  
554 observed. Consequently, such bulk measurements might not be very useful in constraining the biogenicity  
555 of the microstructures, however their carbonaceous composition and syngenetic origin is supported by  
556 Raman microspectroscopy. Based on their taphonomy and for the Paleoproterozoic uncommonly large size,  
557 Javaux et al. (2010) and Buick (2010). Javaux et al. (2010) concluded that the organic-walled microfossils  
558 might either represent remnants of extinct prokaryotes, colonial envelopes of cyanobacteria, or even  
559 eukaryotes. To unravel the biological affinity of these acritarchs remains the task for future investigations,  
560 which should ideally also aim to identify the microstructures in outcrop samples in order to further constrain  
561 their habitat and explore their possible relationship with the widespread, shallow-water microbial mats of  
562 the Moodies Group.

## 564 **6. Discussion**

### 566 **6.1 Evidence of Paleoproterozoic life in the BGB and comparison to the PGBs**

567 Traces of ancient life in the BGB occur mainly confined to bedded, carbonaceous cherts of the Onverwacht  
568 Group and the siliciclastic deposits of the Moodies Group. Preserved biosignatures in these deposits include  
569 putative microfossils of filamentous, spheroidal, and lenticular shape, stromatolites, and microbial mats.  
570 Filamentous microfossils occur very rarely in cherts of the Onverwacht Group but their biogenicity remains  
571 equivocal (Walsh and Lowe, 1985; Walsh 1992, 2010). The rod-shaped filamentous molds preserved in  
572 early silicified, syndepositional cavities of the Moodies Group resemble in shape and size microbial  
573 filaments and also their depositional context, beneath intertidal microbial mats, supports a biogenic origin  
574 (Homann et al., 2016). Spheroidal microstructures with carbonaceous walls, resembling coccoidal cells,  
575 belong to the most common group of putative microfossils in the Onverwacht Group but the assessment of  
576 their biogenicity is in most cases extremely challenging due to their simple, often symmetrical morphology  
577 that can be easily generated abiogenetically in form of e.g. fluid inclusions, vesicles, and spheroidal  
578 crystallites (Schopf and Walther 1983; Brasier et al., 2006). Solely, the spheroidal, cell-like objects reported

579 by Glikson et al. (2008) from the Hooggenoeg Formation and the large, organic-walled spheroids described  
580 by Javaux et al. (2010) from the Moodies Group have a well-established biogenicity. However, the  
581 biological affinity of the latter and the reason for their unusually large size currently remains unknown.  
582 Lenticular structures preserved in the Buck Reef Chert (Walsh 1992; Oehler et al., 2017) and probably also  
583 other cherts of the upper Onverwacht Group (Pflug 1966, 1967; Pflug et al., 1969) belong to the earliest  
584 reported and currently best studied microfossils in the BGB. Remains of these, likely planktonic,  
585 microorganisms have also been reported from the 3.45 Ga Strelley Pool Formation and the ~3 Ga Farrel  
586 Quartzite in the Pilbara Craton where their biogenicity is reasonably well established (e.g. Oehler et al.,  
587 2009, 2017; Sugitani et al. 2007, 2010, 2013; House et al., 2013; Kozawa et al., 2018). The morphologically  
588 similar specimens from Australia occur in the same depositional context and show strikingly similar mean  
589  $\delta^{13}\text{C}_{\text{org}}$  values ( $-37.0\%$  and  $-36.1\%$ ) in comparison to their South African counterparts with a mean  $\delta^{13}\text{C}_{\text{org}}$   
590 value of  $-37.3\%$  (Oehler et al., 2017). Abiogenic models for the formation of similar-looking structures  
591 derived from reworked vesicular volcanic glass exists (Wacey et al., 2018a, 2018b), however these pseudo-  
592 fossils do not resemble the same morphological and microstructural complexity (Alleon et al., 2018;  
593 Kozawa et al., 2018). Nevertheless, the occurrence of such pseudo-fossil examples highlights again the  
594 paramount importance of detailed micro- and nanoscale analysis in the evaluation of the biogenicity of  
595 putative microfossils. Additionally, future studies of microfossil-bearing cherts of the Onverwacht Group  
596 should always be accompanied by detailed analysis of the stratigraphic context and depositional facies, in  
597 combination with *in situ* geochemical analysis of the microfossils themselves and their encasing mineral  
598 matrix.

599 Stromatolites, generally considered as the most ancient macroscopically-visible traces for life on Earth, are  
600 surprisingly rare and currently not as well documented in the BGB in comparison to the PGBs, where the  
601 oldest unequivocal biogenic examples occur preserved in the 3.45 Ga Strelley Pool Formation (Allwood,  
602 et al 2006) and possibly also in the 3.48 Ga Dresser Formation (Fig. 16; Walter et al., 1980; Van  
603 Kranendonk et al., 2008). However, the often morphological very simple, laminated, domal to conical  
604 structures of Archean stromatolites can be easily confused with secondary abiogenic structures, especially  
605 in the absence of indicative microfossils. A recent study of Allwood et al. (2018), highlighting the  
606 importance of morphological analysis in combination with geochemistry at appropriate scales, serves as a  
607 cautionary tale and strongly questions the biogenicity of previously reported putative stromatolites from  
608 3.7 Ga old metacarbonate rocks of Greenland (Nutman et al., 2016). Compared to the greenstone belts in  
609 the Pilbara region, the documented deposit of the BGB contain only minor evidence of early carbonate  
610 environments, which is probably related to the predominance of volcanic and clastic deposition in  
611 combination with high sedimentation rates that made the conditions for stromatolite formation less  
612 favorable.

1009  
1010  
1011 613 The most widespread, pervasive, and probably also oldest trace of ancient life in the BGB are the remnants  
1012 614 of shallow-water microbial mats and biofilms. Mat-like laminations occur in almost all black-and-white-  
1013 615 banded, carbonaceous cherts of the Onverwacht Group (Walsh 1992), but only the examples reported from  
1014 616 the 3.472 Ga Middle Marker (Hickman-Lewis, et al, 2018), the 3.416 Ga Buck Reef Chert (Walsh and  
1015 617 Lowe, 1999; Tice and Lowe, 2004a, 2006a, b; Tice, 2009; Tice et al., 2011), and the 3.334 Ga Josefsdal  
1016 618 Chert (Westall et al., 2011, 2006, 2011, 2015) are reasonably well studied to support their biogenic origin.  
1017 619 Especially the mats and microfossils preserved in the up to 400-m-thick Buck Reef Chert represent a  
1018 620 particularly widespread (~50 km along strike), well-preserved and -documented record of the Paleoproterozoic  
1019 621 life. Besides the necessity to carefully reinvestigate more potentially microfossil- and mat-bearing  
1020 622 carbonaceous cherts in the BGB it is also crucial to further support the already existing claims for early life  
1021 623 from these units with more detailed geochemical analysis such as e.g. carbon, nitrogen, and sulphur isotope  
1022 624 data. The microbial mats preserved in the tidal and fluvial sandstones and conglomerates of the 3.22 Ga  
1023 625 Moodies Group are unique and currently not known from equivalent deposits from Australia (Fig. 16;  
1024 626 Noffke et al., 2006; Heubeck, 2009; Gamper et al., 2012; Homann et al., 2015, 2018). The quality of  
1025 627 preservation of the delicate carbonaceous mat laminae, distinct morphotypes, and mat-associated cavities  
1026 628 in these coarse-grained and gravely siliciclastic deposits is truly exceptional and implies a rapid fossilization  
1027 629 driven by early diagenetic silicification of the sediments (Heubeck 2009; Homann et al., 2015). The  
1028 630 observed difference in the biogeochemical cycling of carbon and nitrogen in tidal marine and fluvial  
1029 631 microbial mats from the Moodies Group (Homann et al., 2018) has demonstrated the potential of detailed  
1030 632 geochemical analysis, which can give valuable insights in the different carbon fixation pathways and  
1031 633 ultimately helps to constrain the metabolism(s) of the mat-building microbial communities and should  
1032 634 consequently also be applied more extensively to the mats preserved in the Onverwacht Group.

## 6.2 Habitats and paleoecology

1045 636  
1046 637 Evidence for Paleoproterozoic life in the BGB have been reported from a wide range of paleoenvironments  
1047 638 including shallow marine (e.g. Byerly et al., 1986; Tice and Lowe, 2004a; Heubeck 2009; Homann et al.,  
1048 639 2015), fluvial (Homann et al., 2018), hydrothermal (Glikson et al., 2008; Westall et al., 2015), and possibly  
1049 640 planktonic settings (Walsh 1992; Oehler et al., 2017), as well as from cryptic cavities in the shallow  
1050 641 subsurface of intertidal deposits (Homann et al., 2016). Due to the general restriction of microbial mats to  
1051 642 shallow-water, photic zone paleoenvironments of the BGB, the common notion is that they were at least in  
1052 643 part composed of photosynthetic microbial communities and already had a high level of UV radiation  
1053 644 tolerance, while the microorganisms thriving in a hydrothermal context or in cavities were likely dominated  
1054 645 by chemotrophic communities. Nearly all of these early microbial communities must have been severely  
1055 646 affected by distant impacts of large asteroids (20 to 50 km in diameter), which occurred between 3.470 Ga  
1056  
1057  
1058  
1059  
1060  
1061  
1062  
1063  
1064

1065  
1066  
1067 647 and 3.225 Ga and are recorded in the BGB deposits by eight known ejecta layers (Fig. 2; Lowe and Byerly,  
1068 648 1986, 2018; Lowe et al., 1989). Besides impact-generated tsunamis it has been proposed that some of these  
1069 649 catastrophic events might have been large enough to cause partial boiling and sterilization of the oceans  
1070 650 and possibly triggered mass extinctions of low-temperature microbes, including most photosynthetic  
1071 651 microorganisms (Sleep et al., 1989; Lowe and Byerly, 2015). The question of how exactly early life  
1072 652 managed to survive these events or if the global ecosystem got entirely destroyed and biogenesis was reset  
1073 653 currently remains open.

1077 654 The Moodies Group ecosystem was particularly diverse, advanced, and well-adapted and includes large  
1078 655 spheroidal microfossils, Earth's earliest evidence of cavity-dwelling microbes (coelobionts), widespread  
1079 656 intertidal tufted microbial mats, laterally traceable for 15 km in a ~1000 m-thick succession, as well as  
1080 657 erosion-resistant fluvial microbial mats. The latter represent the oldest known direct fossil evidence for  
1081 658 terrestrial life on the continental surface and are ~500 Ma older than ~2.7 Ga old fluvio-lacustrine  
1082 659 stromatolites and coelobionts preserved in the Fortescue Group (Tumbiana and Hardey Formation,  
1083 660 Australia; Buick, 1992; Awramik and Buchheim, 2009; Rasmussen et al., 2009; Coffey et al., 2013) and  
1084 661 fluvial stromatolites documented in the Ventersdorp Supergroup (South Africa; Buck, 1980). Based on the  
1085 662 apparent morphological similarities between the shallow-marine microbial mats of the Moodies Group and  
1086 663 modern cyanobacterial mats such as e.g. macroscopic tufts, evidence for gas production and accumulation  
1087 664 in bubbles and domes, and their widespread occurrence and presumably fast growth rate, it has been  
1088 665 proposed that they were perhaps build by ancestral cyanobacteria (Homann et al., 2015). A recent molecular  
1089 666 clock study by Cardona et al. (2018) supports this interpretation and suggest that a primordial photosystem  
1090 667 capable of oxidizing water to oxygen could have formed before the most recent common ancestor of  
1091 668 cyanobacteria. Additionally, also the unusually large size of the organic-walled microfossils reported by  
1092 669 Javaux et al. (2010) indirectly suggests the requirement and the availability of oxygen at 3.22 Ga, although  
1093 670 no unequivocal geochemical signs for the local presence of free oxygen have been found so far in the  
1094 671 Moodies Group.

1103 672

## 1105 673 **7. Conclusions**

1106 674 The deposits of the Barberton Greenstone Belt host a large variety of convincing macro- and microscopic,  
1107 675 as well as geochemical evidence for early microbial life. It was predominantly thriving in shallow marine  
1108 676 environments in the photic zone but started to spread out to colonize fluvial habitats in emerged continental  
1109 677 surface environments and also occupied the first ecological niches, such as subsurface cavities. Traces of  
1110 678 ancient life in the BGB occur scattered throughout the entire stratigraphy confined to carbonaceous cherts  
1111 679 of the Onverwacht Group and siliciclastic deposits of the Moodies Group. However, their identification is  
1112 680 sometimes solely based on morphological attributes and not always accompanied by detailed and systematic

1116  
1117  
1118  
1119  
1120

1121  
1122  
1123 681 geochemical analysis at appropriate scales, which should be improved in future investigations. Due to their  
1124 682 wealth of remarkably preserved microbial mats and microfossils, consistent lateral exposure for several  
1125 683 tens of kilometers and thick stratigraphy, especially the deposits of the 3.416 Ga Buck Reef Chert and the  
1126 684 sandstones of the 3.22 Ga Moodies Group represent a unique window into a diverse Paleoproterozoic  
1127 685 biosphere.  
1128  
1129 686 Based on its universal and outstanding geological and paleobiological value the Barberton-Makhonjwa  
1130 687 Mountains were inscribed in the UNESCO World Heritage Site register in 2018, which will ultimately help  
1131 688 to protect these exceptional outcrops for future studies of Earth's early evolution.

Fig. 1. Geological map of the Barberton Greenstone Belt (BGB) of South Africa and Swaziland and its surrounding plutons in the eastern part of the Kaapvaal Craton. The Barberton Supergroup comprises from base to top the Onverwacht, Fig Tree, and Moodies Group.

Fig. 3. Photomicrographs of carbonaceous laminations from silicified volcaniclastic sediments of the 3.47 Ga Middle Marker interpreted as remnants of microbial mats. A) Multi-layered mats on horizontally-laminated and cross-bedded sediments, disrupted by secondary fracture. B) Close-up view of crinkly, 'micro-tufted' laminations. C and D) Laminations with secondary 'pseudo-tufted' morphology (arrows), which likely formed due to plastic deformation. *Images (A-D) from Hickman-Lewis et al. (2018).*

Fig. 4. Photomicrographs of morphologically diverse types of carbonaceous laminations preserved in the 3.42 Ga Buck Reef Chert and interpreted as fossil microbial mats. A and B) Alpha-type laminations loosely draping trapped grains (arrows) and overlain by detrital sediment layer with eroded mat fragment. C and D) Beta-type laminations with fine meshworks of filament-like strands that drape underlying detrital carbonaceous and silica grains (arrow). E) Gamma-type laminations dissected by early diagenetic silica veins subparallel to bedding (arrow), likely formed due to fluid escape from the sediment. F) Close-up view showing flat carbonaceous laminations, which tightly drape a detrital grain (arrow). *Images (A-F) from Tice (2009).*

Fig. 5. Photomicrographs of eroded and rolled-up microbial mat fragments from the Buck Reef Chert. A) Close-up view of boxed area in Fig. 4A showing a plastically-deformed segment of alpha-type mat. B) Large, rolled-up fragment of a beta-type mat. *Image (A) from Tice (2009) and (B) from Tice and Lowe 2006b.*

Fig. 6. Photomicrographs of microbial biofilms preserved in the 3.33 Ga Josefsdal Chert. A) Wispy anastomosing laminations that coat and stabilize the underlying sediments. B and C) Close-up views of the fine carbonaceous layers. D) Partially eroded fragments facing down and upwards (arrows) indicate pliable consistency of the biofilms. *Images (A-C) from Westall et al. (2011); Image (D) from Westall et al. (2015).*

Fig. 7. Photomicrographs of filamentous microstructures from the Buck Reef Chert (Kromberg Formation). A) Interwoven clumps of filamentous microfossils. B) Hollow cylindrical filaments oriented subparallel to bedding. C) Solitary, slightly twisted hollow filament. *Image (A) courtesy of Maud M. Walsh; Image (B) from Walsh (2000); Image (C) from Walsh (1992).*

Fig. 8. Photomicrographs of lenticular structures interpreted as microfossils. A-D) Lenticular, disk-shaped objects with hollow centers and carbonaceous walls preserved in cherts from the Upper Onverwacht Group. Note that the structures occur isolated or in chain-like clusters of several specimen. (E-H) Morphologically very similar lenticular microfossils from the Buck Reef Chert. *Images (A-D) from Pflug (1966); Images (E-H) from Oehler et al. (2017), courtesy of Dorothy Z. Oehler.*

Fig. 9. Photomicrographs of proposed spheroidal microfossils from cherts of the Onverwacht Group. A and B) Transmission electron microscopy (TEM) images of cell-like objects with granular, in places detached walls (arrow) from the Hooggenoeg Formation. C and D) Large spheroids and ellipsoids from the Buck Reef Chert. E and F) Clusters of thin-walled spheroids from the Buck Reef Chert. G and H) Groups of spheroidal microstructures with rounded to angular walls from the Buck Reef Chert. I) Putative organic microspheres (arrows) from the Msauli Chert, which show features resembling cell division (small image in the upper right corner). Images (A-D) from Glikson *et al.* (2008); Images (C-F) from Walsh (1992); Images (G and H) from Kremer and Kazmierczak (2017); Image (I) courtesy of Andrew H. Knoll.

**Fig. 10.** Putative stromatolites and laminated silica crusts from the upper Onverwacht and Fig Tree Group. A) Polished slab showing morphologically diverse stromatolites overlying and draping the brecciated top of a komatiitic lava flow. Small basal domes successively grade into pseudocolumnar stromatolites with bridging laminations that are, in turn, overlain by low-relief domal laminations. Note the eroded stromatolite chips adjacent to the basal dome (arrow). B) Laminated silica crusts with inclined stromatolite-like columns and domes. C) Photomicrograph showing fine primary carbonaceous laminae with variable enrichment in secondary fine-grained tourmaline (dark minerals). D) Conglomerate of laminated silica chips interpreted as fragments of eroded stromatolites or sinter crusts. *Images (A and C) from Byerly and Palmer (1991), (B and D) from Lowe and Byerly (2018).*

Fig. 11. Comparison of fossil microbial mats from tidal marine (A, B) and fluvial (C) deposits of the 3.22 Ga Moodies Group. A, B) Polished slab photographs of marine mats from the Saddleback Syncline showing densely spaced, crinkly carbonaceous laminations with small domes and tufts. The fossil mats are interbedded with medium- to coarse-grained sandstone and in places underlain by bedding-parallel chert lenses interpreted as silicified cavities. C) Terrestrial mats from the fluvial deposits of the Dycedale Syncline draping and onlapping interbedded clasts. Note that the preserved carbonaceous laminae are often thicker in comparison with the marine mats.

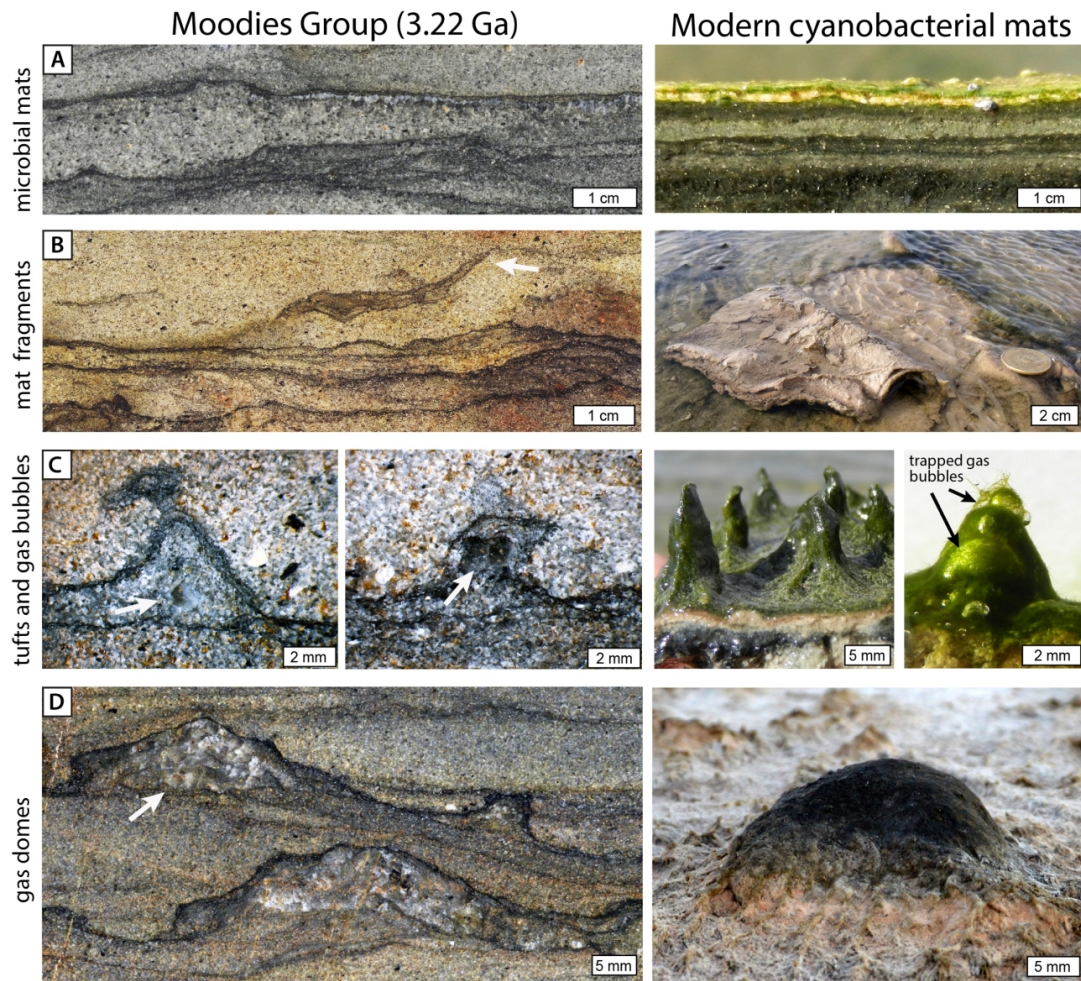

Fig. 12. Comparison of fossil intertidal microbial mats from the 3.22 Ga Moodies Group (left) with modern cyanobacterial mats from the tidal flats of Bahar Alouane, Tunisia (right). A) Crinkly carbonaceous mat laminations. B) Eroded mat fragment (arrow) and roll-up structure indicative for a cohesive consistency. C) Microbial tufts with now silicified cavities (arrows) interpreted as fossil gas bubbles, resembling trapped oxygen-rich bubbles in modern tufted mats. D) Silicified gas domes beneath the Moodies mats (arrow) and modern analogue of similar shape and size from Tunisia.

Fig. 13. Fossil terrestrial microbial mats from fluvial sandstones and conglomerates of the Moodies Group. A) Field photograph of the fluvial mats (arrow) interbedded with gravelly sandstones. B) Microbial mats disrupted and deformed by subvertical fluid-escape structure with well-defined central channel (arrow). C) Polished slab photograph with dark carbonaceous laminae of the fossil mats, draping former sedimentary surfaces and overlapping pebbles. D) Close-up view of the laminae, which show a dense meshwork of interwoven filamentous microstructures with trapped detrital grains. E) Filament-like microstructures in the upper, partially eroded part of the mat. *Images (A-E) from Homann et al. (2018).*

Fig. 14. Evidence for cavity-dwelling microbial life in the tidal deposits of the Moodies Group. A) Polished slab photograph showing silicified bedding-parallel cavity beneath fossil microbial mat (arrow). B) Photomicrograph of the silicified cavities with carbonaceous laminations, wisps, and pendant protrusions at the cavity ceiling (arrows). C) Carbonaceous laminae surrounding ovoid-shaped structure interpreted as trapped gas bubble (arrow). D and E) Close-up view of downward-facing columnar microstromatolites with preserved internal carbonaceous laminae. F) SEM image showing meshwork of filament molds embedded and permineralized in chert. G and H) Filamentous molds with regularly, spaced, rod-shaped segments of approximately similar length. *Images (B and D-H) from Homann et al. (2016).*

Fig. 15. Large organic-walled microfossils from the Moodies Group. A and B) Compressed spheroidal structures (arrows) in petrographic thin section. C and D) Microstructure extracted from the rock by acid maceration showing concentric folding (arrow in C) and collapse (arrow in D) of the wall. E) SEM image showing the folded, wrinkled and degraded texture of the wall (arrow). F) TEM image of ultrathin section showing homogenous ultrastructure of the torn and wrinkled 'cell' wall. *Images (A-F) from Javaux et al. (2010).*

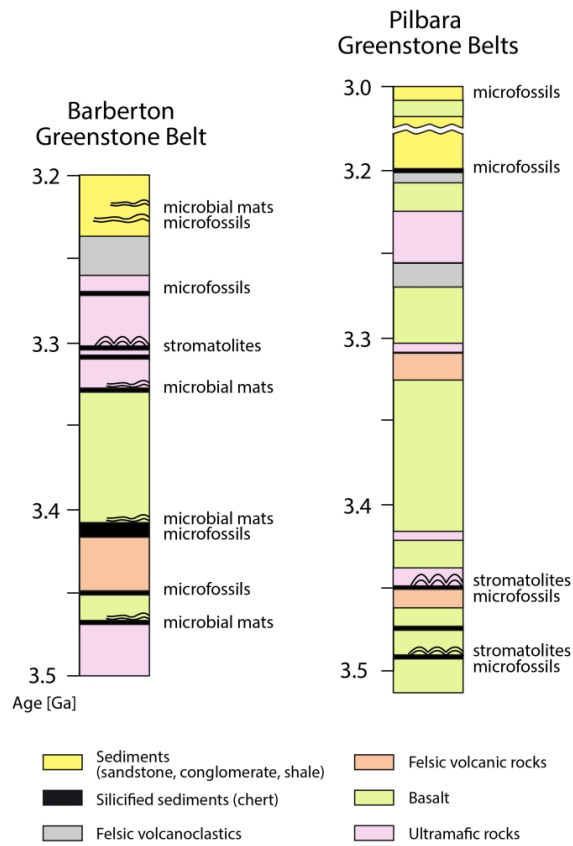

Fig. 15. Simplified stratigraphy and traces of early life in the Barberton Supergroup of South Africa in comparison with the Pilbara Supergroup of Western Australia.

**Table 1 | Claims for Paleoproterozoic Life in the Barberton Greenstone Belt, South Africa**

Age [Ma]	Lithostratigraphic Unit	Paleoenvironment	Morphological Evidence	Geochemical Evidence	Comments
~3220†	<b>Moopies Group</b>	Tidal marine coastline	<b>Microbial mats:</b> densely-spaced carbonaceous laminae interbedded with tidal sandstones (Nothke et al., 2006; Heubeck 2009; Gampert et al., 2012), cohesive erosion-resistant behavior, distinct mat morphologies (planar, crinkly, tufted); fossil gas bubbles, shrinkage cracks, eroded and reworked mat fragments, mm- to cm-sized silicified gas domes, and widespread fluid-escape structures (Homann et al., 2015).	$Bulk \delta^{13}C_{org}$ : -33.9‰ to -21.3‰ (n=30) $Bulk \delta^{15}N$ : -0.7‰ to +3.1‰ (n=9) Raman $T_{max}$ : ~366°C	Well-established depositional, and petrographic context, widespread occurrence (15 km along strike), facies dependent mat morphology, combined with evidence for biogeochemical cycling of carbon and nitrogen strongly suggest a biogenic origin (Homann et al., 2018).
~3250	<b>Fig Tree Group</b> Sheba Fm.	Shallow-marine deltaic?	<b>Organic-walled microfossils:</b> of carbonaceous composition preserved in shales and siltstones, spheroidal shape (up to 300 µm in diameter), cellular morphology and ultrastructure, occurrence in populations (Javaux et al., 2010; Butck, 2010).	$Bulk \delta^{13}C_{org}$ : -28.3‰ to -16.4‰ (n=22)	A promising sign for life, carbon isotopes would be more convincing if measured in situ on individual microfossils.
		Braided fluvial to supratidal	<b>Paleosols:</b> containing pedogenic carbonates, sulfates, and pyrite grains with biogenic overgrowth rims (Nabhan et al., 2016a, b).	$In situ \delta^{34}S_{C-DTE}$ : -25‰ and -20‰ (n=105) suggestive for microbial fractionation of sulfur	Detailed stratigraphic and petrographic context support Earth's oldest known signs for biogenic sulfur cycling on land.
		Fluvial, coastal braidedplain	<b>Microbial mats:</b> of carbonaceous composition (Homann et al., 2018), draping gravely sandstone beds and conglomerates of fluvial-alluvial origin (Heubeck and Lowe, 1994; Eriksson et al., 2006; Heubeck et al., 2016) associated with desiccation cracks, eroded mat fragments and fluid-escape structures.	$Bulk \delta^{13}C_{org}$ : -23.6‰ to -17.9‰ (n=36) $Bulk \delta^{15}N$ : +1.9‰ to +5.6‰ (n=10) Raman $T_{max}$ : ~363°C	Earth's earliest combined fossil and geochemical evidence for the microbial colonization of terrestrial habitats on the emergent continental landmass.
3298±	<b>Onverwacht Group</b> Mendon Fm. (M2c)	Shallow-water to subaerial, evaporitic	<b>Stromatolites:</b> with tourmaline-rich, carbonaceous laminae preserved in cherts as laterally linked, low-relief domes (1–3 cm wide, 0.5–3 cm high) and compound domes or pseudocolumns of up to 10 cm height (Byerly et al., 1986; Byerly and Palmer, 1991). Fragments of eroded stromatolites or sinter crusts (Lowe and Byerly 2015, 2018).	None, except carbonaceous composition	Widespread (<10 km along strike) and morphological diverse. Possibly Africa's oldest stromatolites, but more evidence needed.
	Mendon Fm.* (previously named Swartkoppie Fm.)	?	<b>Possible microfossils:</b> lenticular [spindle-shaped] (30–70 µm in long axis) and spheroidal (5–50µm) shapes preserved in chert, occurrence as individuals or in clusters and chains, which might resemble remains of former colonies (Pflug 1966, 1967; Pflug et al., 1969). *Cherts were originally assigned to the Fig Tree Group.	None, except carbonaceous microfossil walls	Possible life, but geological context and geochemistry needed to further support biogenic origin.
	Mendon Fm.*	?	<b>Possible microfossils:</b> spheroidal structures, ~19 µm in diameter (Barghoorn and Schopf, 1966; Schopf and Barghoorn, 1967).	None, except carbonaceous microfossil walls	Simple morphology, and no depositional context or geochemistry reported. Could likely be non-biological (Wacey, 2009).
	Mendon Fm. (M1c) (Msauti Chert)	Shallow-marine to nearshore	<b>Possible microfossils:</b> spheroidal structures (1–4 µm in diameter) showing possible cell division (Knoll and Barghoorn, 1977).	None, except carbonaceous microfossil walls	Possible life, but hydrothermal fluids can mobilize and redistribute organic matter into spheruloids (Knoll et al., 2016). High-resolution analysis needed to support biogenicity.

Age [Ma]	Lithostratigraphic Unit	Paleoenvironment	Morphological Evidence	Geochemical Evidence	Comments
3334 <sup>2</sup>	Kromberg Fm. (K3) (Loseisdal Chert)	Nearshore, possibly hydrothermal	<b>Microbial mats:</b> carbonaceous laminae (~10µm thick) in layered packets of 100–1000 µm thickness; eroded fragments of biofilms. (Westall et al., 2001; 2006; 2011; 2015). Putative rod-shaped microfossils are probably abiogenic (Altermann, 2001; Wacey 2009).	<i>Bulk</i> $\delta^{13}C_{org}$ : -26.8‰ and -22.7‰ (n=2) <i>In situ</i> : $\delta^{13}C_{org}$ : -45‰ to -13‰ $\delta^{34}S$ : -2.4‰	Petrographic observations and geochemical signals support the biogenic origin.
3416 <sup>3</sup>	Kromberg Fm. (K1) (Buck Reef Chert)	shallow-marine	<b>Microbial mats:</b> fine carbonaceous laminae with different morphotypes, draping underlying sediments and detrital particles; filaments (1–1.5 µm in diameter), rolled-up fragments; carbonaceous grains (Walsh and Lowe, 1999; Tice and Lowe, 2004a, 2006a, b; Tice, 2009; Tice et al., 2011). <b>Probable microfossils:</b> lenticular structures (1.3–1.35 µm long and 4.5–61 µm wide) with hollow center, interpreted as remnants of possibly planktonic microbes (Walsh, 1992; Oehler et al., 2017). Similar structures also occur in cherts of the Pilbara Craton. <b>Possible microfossils:</b> filamentous structures (1.2–1.4 µm in diameter), sometimes interwoven clumps spheroidal structures (1.0–84 µm and 4.5–12.8 µm in diameter) (Walsh and Lowe, 1985; Walsh 1992, 2000)	<i>Bulk</i> $\delta^{13}C_{org}$ : -36.9‰ and -20.1‰ (n=19) <i>In situ</i> $\delta^{13}C_{org}$ : -39.3‰ to -35.5‰ (n=8) None, except carbonaceous composition	Widespread, well-documented, and morphological complex evidence for life. Depositional context, morphological complexity, and narrow range of $\delta^{13}C_{org}$ values support a biological origin. High-resolution petrographic and <i>in situ</i> carbon isotope analysis needed.
3416 <sup>3</sup>	Kromberg Fm. (K1c2) (Buck Reef Chert)	shallow-marine	<b>Possible microfossils:</b> spheroidal (3–12 µm in diameter) interpreted as remains of beuthic-planktonic microbes, resembling coccolidal cyanobacteria (Kremer and Kazmierczak, 2017).	<i>Bulk</i> $\delta^{13}C_{org}$ : -26.5‰ and -24.3‰ (n=2)	Morphologically simple structures with angular terminations. Nanoscale analysis and <i>in situ</i> geochemical data needed.
~3450	Kromberg Fm. and Hoogenoeg Fm.	Submarine pillow basalts	<b>Possible trace fossils:</b> filament-shaped and titanite-mineralized microtubes (4 µm in diameter and up to 200µm in length) in glassy pillow lava rims (Furnes et al., 2004). Similarity to microtubes from recent pillow lavas, but even their microbial origin is debated (Wacey et al., 2017).	<i>Bulk</i> $\delta^{13}C_{carb}$ : -16.4‰ to +3.9‰ <i>In situ</i> $\delta^{34}S_{CDT}$ : -40‰ to -3‰ from pyrite	Syn- and biogenicity questioned by Grosch and McLaughlin (2014) and Grosch et al. (2016), structures likely formed abiotically during post depositional contact metamorphism.
	Hoogenoeg Fm.	?	<b>Possible microfossils:</b> spheroidal and cup-shaped structures; 5–106 µm in diameter (Engel et al., 1968).	None, except carbonaceous composition	Probably of non-biological origin (Nagy and Nagy, 1969; Schopf and Walter, 1983). Promising sign for life, but no geochemical data.
3470 <sup>4</sup>	Hoogenoeg Fm. (H3c, H5c)	Seafloor, possibly hydrothermal	<b>Possible microfossils:</b> spheroidal structures (2–10 µm in diameter) with granular 'cell' walls interpreted as remnants of chemosynthetic microbes (Glikson et al., 2008). Morphological similarity to modern hyperthermophilic microbes.	None	Promising sign for life, but no geochemical data.
3472 <sup>5</sup>	Hoogenoeg Fm. Middle Marker (H1)	Shallow marine, associated with volcanic activity	<b>Microbial mats:</b> fine, crinkly to micro-tufted laminations, 'trapped' detrital sediment, wisp-like microstructures interpreted as eroded biofilm or mat fragments (Hickman-Lewis et al., 2018).	None, except carbonaceous composition and RIE data	Carbon isotope data needed to further support biogenicity of the possibly most ancient trace of life in the BCB.
