Abstract :

A set of realistic coastal coupled ocean-wave numerical simulations is used to study the impact of surface gravity waves on a tidal temperature front and surface currents. The processes at play are elucidated through analyses of the budgets of the horizontal momentum, the temperature, and the turbulence closure equations. The numerical system consists of a 3D coastal hydrodynamic circulation model (Model for Applications at Regional Scale, MARS3D) and the third generation wave model WAVEWATCH III (WW3) coupled with OASIS-MCT at horizontal resolutions of 500 and 1500 m, respectively. The models were run for a period of low to moderate southwesterly winds as observed during the Front de Marée Variable (FromVar) field campaign in the Iroise Sea where a seasonal small-scale tidal sea surface temperature front is present. Over the 2 day period considered, long fetch waves grow gradually propagating north east and east.

Contrasting a stand-alone ocean run with a coupled ocean-wave run shows that waves move the Ushant front offshore by up to 4 kilometres and cool the offshore stratified side of the front by up to 1.5°C. The analysis of the temperature budget shows that the change in advection is the dominant factor contributing to the frontal shift while the contribution of wave enhanced vertical temperature diffusion is secondary. Temperature, considered to be a tracer, is advected in the coupled run by the Lagrangian current resulting from the quasi-Eulerian and Stokes drift. Although the Stokes drift is directed shorewards, changes in the quasi-Eulerian current lead to a more offshore advection in the coupled than the stand-alone run. The quasi-Eulerian current is reduced (enhanced) during the ebb (flood) flow which correspond to periods of wave-following (-opposing) currents. This is due to wave breaking enhanced vertical mixing acting on the positive vertical gradient present in the quasi-Eulerian current during both ebb and flood tides. Partially coupled runs reveal that it is the surface flux of TKE associated to wave breaking that is key rather than the changes in the surface stress. They further elucidate the role of other modelled wave related processes. Although the contribution of the Stokes–Coriolis force and the wave breaking induced enhancement in vertical mixing to the quasi-Eulerian current are of similar magnitude and sign, it does not contribute significantly to the frontal shift. This is because it partially counters the Stokes drift advection which pushes the front shorewards. All Stokes drift related processes combined thus only lead to a very slight displacement of the front.

Highlights

► A novel ocean-wave coupled modelling and analysis framework was developed. ► Realistic high resolution numerical simulations reveal wave–current interactions. ► Wave enhanced mixing reduces or enhances surface currents when following or opposing. ► Waves alter the position of the surface temperature tidal front in the Iroise Sea. ► Wave-ocean dynamics and kinematics in a tidally driven coastal ocean are described.

Keywords : Ocean-wave coupling, Coastal coupled modelling, Current–wave interactions, Tidal front, Iroise Sea

1. Introduction

In recent years much effort has been dedicated to understanding and quantifying the impacts of surface gravity waves on upper ocean currents and mixing as these can have significant physical and biogeochemical consequences (see *Sullivan and McWilliams, 2010; Cavaleri et al., 2012; Villas Boas et al., 2019*, and references therein). The impacts in coastal seas are particularly relevant to a wide range of scientific questions and applications (*Cavaleri et al., 2018*). Modeling wave-current interactions in coastal environments presents many challenges since they are governed by the interplay of multiple phenomena spanning a wide range of spatio-temporal scales.

Waves alter the momentum and energy input to the upper ocean. They take up a portion of the wind input as they grow and release some to the ocean as they break. They generate a mean Lagrangian current in the direction of wave propagation known as the Stokes drift. On the rotating earth, the Stokes drift is affected by the Coriolis force inducing a current perpendicular to wave propagation and a transport that compensates the Stokes drift over an inertial period (*Hasselmann, 1970; Xu and Bowen, 1994*). Interaction between the Stokes drift velocity and the mean-flow vorticity results in the Stokes vortex force (*Craik and Leibovich, 1976; Lane et al., 2007*). The persistent vertical shear of the Stokes drift tilts the vertical component of the vorticity that is perpendicular to the wind into the wind direction. This promotes the generation of rolls aligned with the wind known as Langmuir circulations (*Langmuir, 1938*). A thorough overview of the effects of the Stokes drift on currents can be found in *Suzuki and Fox-Kemper (2016)*. Wave breaking, Langmuir circulations, Stokes drift interaction with the Coriolis force, and stirring by non-breaking waves all contribute to upper-ocean mixing and turbulence (*Wu et al., 2015*) as shown from measurements of the dissipation of the turbulent kinetic energy (*Agrawal et al., 1992; Terray et al., 1996*).

A common and highly predictable feature of coastal oceans are tidal fronts. These surface temperature fronts separate cold shallow waters nearshore where tidal friction produces enough turbulence to constantly mix the entire water column and warm waters offshore over depths where tidal mixing is not sufficient to erode the seasonal thermocline. They appear in the spring and erode at the end of autumn. Such fronts present convergence zones associated with wave steepening and breaking (*Baschek et al., 2006*). How in turn waves alter ocean currents, temperatures, and mixing around tidal fronts has not been studied in great detail because wave forcing is secondary to tidal forcing. The wave adjustment of geostrophic fronts was studied by *McWilliams and Fox-Kemper (2013)* and *Suzuki et al. (2016)* showed the importance of the Stokes shear in frontogenesis as they found it to energise the ageostrophic secondary circulations. In these studies, the Stokes drift is of the same order of magnitude as the frontal circulation and both

32 are of the order or larger than the background flow. This is not the case around tidal fronts where the
33 background tidal flow can be an order of magnitude larger than the frontal circulation and the Stokes
34 drift. The set up of tidal fronts depends on the competing stratifying effect of solar radiation and tide
35 driven mixing. Their location is largely determined by the magnitude of the tidal current and the water
36 depth (*Simpson*, 1981). However, wave driven currents and mixing could alter the frontal position as this
37 paper aims to elucidate.

38 Distinguishing wave effects in current measurements is not a straightforward exercise (*Polton et al.*,
39 2005; *Raschle and Ardhuin*, 2009; *Ardhuin et al.*, 2009) and often does not allow for much more than
40 qualitative inferences. Laboratory experiments (*Kemp and Simons*, 1982, 1983; *Klopman*, 1993, 1994)
41 provided insights on how surface waves alter currents. The dynamics they imply have yet to be verified
42 in the field which may be in a different parameter regime and their existence in the real or modeled
43 ocean needs to be assessed. Theoretical frameworks provide insights into key physical processes but the
44 high complexity of the system does not allow to go much beyond asymptotic behaviour (*McWilliams*
45 *et al.*, 2004) and specific equilibria (*McWilliams and Fox-Kemper*, 2013; *Song*, 2009). Numerical methods
46 allow to better understand the processes at play. However, asymptotic approaches and parameterisations
47 remain necessary in models. One dimensional (vertical) models have been used to study wave modification
48 to the Ekman current trying to reproduce in situ current shear measurements (*Raschle et al.*, 2006; *Raschle*
49 *and Ardhuin*, 2009). Large eddy simulations (*Polton et al.*, 2005; *McWilliams and Fox-Kemper*, 2013;
50 *Sullivan et al.*, 2007; *Suzuki et al.*, 2016) and direct numerical simulations (*Sullivan et al.*, 2004) remain
51 idealistic and only represent a subset of wave related processes.

52 To investigate the multitude and complexity of processes at play in the coastal oceans, realistic fully-
53 coupled ocean-wave simulations are needed. In coupled modeling, the inclusion of wave processes heavily
54 relies on parameterizations. Also, the representation of wave-current interactions is simpler than in the
55 above mentioned theoretical work. They are, however, largely based on assumptions supported by those
56 ‘idealised’ approaches and coupled simulations can provide a broader view of the processes at play. To
57 date, several coupled model frameworks have been developed and exploited to study the impact of waves
58 on currents in coastal seas (*Osuna and Wolf*, 2005; *Bolaños et al.*, 2014; *Ràfols et al.*, 2019). While
59 *Bolaños et al.* (2014) concluded that waves do not significantly alter the tidally dominated component of
60 the current but improved the transverse current component, *Osuna and Wolf* (2005) showed large effects
61 of waves on currents especially where the currents are strong and sheared. *Ràfols et al.* (2019) reported
62 no substantial differences in the water current field between coupled and uncoupled simulations.

63 It is important to note here that to date the majority of studies, be it theoretical, numerical, or

64 experimental, have focused on cases where the Stokes drift is comparable or stronger than the background
65 flow. Filling this gap, a new set of coupled model experiments were undertaken focusing on the Iroise
66 Sea which provides an excellent natural laboratory to study interactions between the waves, the ocean,
67 and the atmosphere in strongly tidally forced conditions. Located in the North Atlantic, off the coast of
68 Brittany, France, the Iroise Sea is subject to long fetch waves and features an intense seasonal surface
69 thermal front: the Ushant tidal front (Fig. 1). It is characterized by a strong surface temperature gradient
70 separating the homogeneous waters of moderate temperatures ($<14^{\circ}\text{C}$) close to the coast and the warm
71 surface ($>16^{\circ}\text{C}$) stratified waters offshore. A second temperature front exists at the bottom separating
72 the waters of the cold “tongue” which covers the continental shelf and the homogeneous waters close to
73 the coast. *Le Boyer et al.* (2009) noted that the two fronts are governed by different dynamics meaning
74 that the two fronts are not always co-located. The position of the surface front varies with the tidal
75 current. It is pushed towards the coast during the flood tide and towards the open sea by the ebb tide.

76 This paper provides a detailed study of the wave-ocean coupling in the Iroise Sea with a focus on
77 the impacts on the currents and surface temperatures around the Ushant front based on a set of realistic
78 forced and coupled coastal model runs. These are described in Section 2 along with an outline of the
79 coupling framework. Key results are presented in Section 3 and discussed in Section 4. The conclusion
80 section summarises the results and processes at play. Finally, it highlights the interest of the proposed
81 model and analysis framework.

82 **2. Model Experiments**

83 In this section, the equations at the heart of the stand-alone ocean model are presented first followed
84 by those used in the coupled configuration. Relevant aspects of the coupling between the ocean and the
85 wave models are detailed exposing how wave related processes are taken into account. These include
86 Stokes drift advection of tracers, Stokes-Coriolis and Stokes vortex forces on the horizontal currents, wave
87 altered surface stress, wave breaking induced turbulence, and wave orbital velocity driven bottom stress.
88 Configurations used for the ocean and wave models are then summarized along with the description of
89 the simulations’ setup. The equations of the wave model with currents are not recalled herein, as the
90 focus of the paper is on the ocean response to waves. These can be found in *Ardhuin et al.* (2017).

91 *2.1. Uncoupled Ocean Model*

92 The ocean model used in this study is the 3D coastal hydrodynamic circulation model MARS3D
 93 (Model for Applications at Regional Scale, *Lazure and Dumas (2008); Lazure et al. (2009)*). MARS3D
 94 resolves the primitive equations for an in-compressible, hydrostatic fluid under the Boussinesq hypothesis.
 95 The temporal evolution of a horizontal current ($\mathbf{u} = u + iv$ in $\mathbf{x} = x + iy$) is modeled as:

$$\frac{\partial \mathbf{u}}{\partial t} = -\mathcal{L}(\mathbf{u}) - if\mathbf{u} + \frac{\partial}{\partial z} \left(K_u \frac{\partial \mathbf{u}}{\partial z} \right) + \frac{d}{d\mathbf{x}} \left(K_{\mathbf{x}} \frac{d\mathbf{u}}{d\mathbf{x}} \right) + \frac{1}{\rho_0} \frac{dP_i}{d\mathbf{x}} - g \frac{d\zeta}{d\mathbf{x}} - \frac{1}{\rho_0} \frac{dP_a}{d\mathbf{x}} \quad (1)$$

96 with the operator $\mathcal{L} = \left(u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w \frac{\partial}{\partial z} \right)$ and the complex derivative: $\frac{d}{d\mathbf{x}} = \frac{\partial}{\partial x} + i \frac{\partial}{\partial y}$. $\mathcal{L}(\mathbf{u})$ represents
 97 the non-linear advection terms, g the acceleration due to gravity, $\rho_0 = 1027.34 \text{ kg m}^{-3}$ the reference water
 98 density, f the Coriolis parameter, K_u the vertical eddy viscosity and $K_{\mathbf{x}}$ the horizontal ones, ζ the sea
 99 surface height, and P_a and P_i the surface atmospheric and internal pressures, respectively. Since the
 100 model assumes the ocean to be hydrostatic, P_i is derived from $\frac{\partial p}{\partial z} = \rho_0 b$ with the buoyancy given by:
 101 $b = -g(\rho - \rho_0)/\rho_0$ and ρ the water density. The vertical velocity follows from continuity. The surface
 102 boundary conditions are given by the zonal and meridional wind stress $\tau_{\mathbf{a}}$ computed from the 10-m wind
 103 (\mathbf{u}_{10}) forcing using:

$$\tau_{\mathbf{a}} = \rho_a C_D \mathbf{u}_{10}^2 \quad (2)$$

104 where C_D is the drag coefficient based on *Charnock (1955)* and ρ_a the surface air density.

105 The evolution of a tracer C is given by the advection-diffusion equation:

$$\frac{\partial C}{\partial t} = - \left(\frac{\partial}{\partial x} [uC] + \frac{\partial}{\partial y} [vC] + \frac{\partial}{\partial z} [wC] \right) + \frac{\partial}{\partial z} \left(K_C \frac{\partial C}{\partial z} \right) + F \quad (3)$$

106 where K_C is the vertical diffusivity (the horizontal ones are set to 0). The source term F consists of
 107 the solar irradiance and long-wave radiation for temperature. The salinity evolves with water fluxes
 108 induced by precipitation minus evaporation as well as river outflows. The surface boundary condition for
 109 temperature diffusion is the latent and sensible turbulent fluxes.

110 The eddy viscosity ($K_u = c_\mu \frac{k^2}{\varepsilon}$) and vertical diffusivity for temperature ($K_C = c'_\mu \frac{k^2}{\varepsilon}$) are obtained
 111 from the two-equation $k - \varepsilon$ model (*Burchard, 1998; Burchard and Bolding, 2001*) which were chosen in
 112 this study for turbulence closure. The *Canuto et al. (2001)* version A (CA) stability functions c_μ and c'_μ
 113 based on the non-dimensional shear and buoyancy numbers as described in *Umlauf and Burchard (2005)*
 114 are used to damp (enhance) turbulence in stably (unstably) stratified conditions. The turbulent kinetic
 115 energy (TKE, k) is modeled as:

$$\frac{\partial k}{\partial t} = -\mathcal{L}(k) + \frac{\partial}{\partial z} \left(\nu_k \frac{\partial k}{\partial z} \right) + P + D - \varepsilon \quad (4)$$

116 where the shear P and the buoyancy D contributions are functions of the vertical shear and the Brunt-
 117 Väisälä frequency, respectively. In the configuration used here, the advection term $\mathcal{L}(k)$ is neglected. The
 118 equation of the TKE dissipation rate (ε) is given by:

$$\frac{\partial \varepsilon}{\partial t} = \frac{\varepsilon}{k} (c_{\varepsilon 1} P + c_{\varepsilon 3} D - c_{\varepsilon 2} \varepsilon) + \frac{\partial}{\partial z} \left(\nu_{\varepsilon} \frac{\partial \varepsilon}{\partial z} \right) \quad (5)$$

119 The empirical constants $c_{\varepsilon i}$ ($= 1.44, 1.92, -0.63$ or 1) are taken from *Burchard and Bolding* (2001) and
 120 *Umlauf* (2003). A positive (negative) $c_{\varepsilon 3}$ is taken for unstable (stable) stratified flows (*Canuto et al.*,
 121 2001). The eddy viscosities ν_k and ν_{ε} are computed through constant Schmidt numbers as: $\nu_{k,\varepsilon} = \frac{K_u}{\sigma_{k,\varepsilon}}$
 122 with $\sigma_k = 1$ and $\sigma_{\varepsilon} = 1.3$.

123 A constant flux condition is used at the sea surface for Eq. (4):

$$\frac{\partial k}{\partial z} = 0 \quad (6)$$

124 For Eq. (5), the Neuman-type surface boundary condition is:

$$\frac{\partial \varepsilon}{\partial z} = (c_{\mu}^0)^{\frac{3}{4}} \frac{k^{\frac{3}{2}}}{\kappa (z_0 + z')^2} \quad (7)$$

125 where $c_{\mu}^0 = 0.077$ (CA), z_0 is the surface roughness length, z' the distance to the surface boundary, and
 126 $\kappa=0.4$ the von Karman constant.

127 2.2. Coupled Wave-Ocean Model Framework

128 The MARS3D has been coupled with the 3rd generation wave model WAVEWATCHIII (WW3, *Tolman*
 129 (2014)), through OASIS-MCT (*Voldoire et al.*, 2017). As listed on the diagram Figure 2, MARS3D sends
 130 3 fields to WW3 and receives 17 fields from WW3. The framework was developed in a way to minimize
 131 the parameterizations of wave dependent variables within the ocean model. Thus coupling as many fields
 132 directly computed from the source function of WW3 and the model wave spectra as possible rather than
 133 relying on say wave height dependent parameterizations. The coupling between WW3 and MARS3D
 134 occurs every 100 s. The coupling module performs distance weighted nearest neighbour interpolations
 135 from one regular model grid to the other based on 4 points using the Los Alamos National Laboratory
 136 SCRIP1.4 library (*Jones*, 1999).

137 The impact of waves on the ocean is modeled following the quasi-Eulerien framework (*Ardhuin et al.*,
 138 2008; *Bennis et al.*, 2011) based on wave-averaged primitive equation limited to second order wave theory.
 139 In the coupled ocean-wave configuration Eq. (1) becomes:

$$\begin{aligned} \frac{\partial \hat{\mathbf{u}}}{\partial t} = & -\hat{\mathcal{L}}(\hat{\mathbf{u}}) - i f \hat{\mathbf{u}} + \frac{\partial}{\partial z} \left(K_u \frac{\partial \hat{\mathbf{u}}}{\partial z} \right) + \frac{d}{dx} \left(K_x \frac{d\hat{\mathbf{u}}}{dx} \right) + \frac{1}{\rho_0} \frac{dP_i}{dx} - g \frac{d\zeta}{dx} - \frac{1}{\rho_0} \frac{dP_a}{dx} \\ & - i f \mathbf{u}_s - i \left(\frac{\partial \hat{v}}{\partial x} - \frac{\partial \hat{u}}{\partial y} \right) \mathbf{u}_s - \frac{\partial \hat{\mathbf{u}}}{\partial z} w_s - \frac{\partial J}{\partial \mathbf{x}} \end{aligned} \quad (8)$$

140 where $\hat{\mathbf{u}}$ is the quasi-Eulerian velocity defined as the difference between the Lagrangian velocity (\mathbf{u}_L) and
 141 the horizontal Stokes drift (\mathbf{u}_s):

$$\hat{\mathbf{u}} = \mathbf{u}_L - \mathbf{u}_s \quad (9)$$

142 Both $\hat{\mathbf{u}}$ and \mathbf{u}_s satisfy continuity. In Eq. (8) $\hat{\mathcal{L}} = \left(\hat{u} \frac{\partial}{\partial x} + \hat{v} \frac{\partial}{\partial y} + \hat{w} \frac{\partial}{\partial z} \right)$ and w_s is the vertical component
 143 of the Stokes drift. New wave dependent terms appear on the right hand side terms of Eq. (8): the
 144 Stokes-Coriolis force ($if\mathbf{u}_s$), the Stokes vortex force ($-i \left(\frac{\partial \hat{u}}{\partial x} - \frac{\partial \hat{v}}{\partial y} \right) \mathbf{u}_s - \frac{\partial \hat{\mathbf{u}}}{\partial z} w_s$), and the wave-induced
 145 Bernoulli head pressure (J , *Smith (2006)*). In this configuration, the model remains hydrostatic and the
 146 impact of the Stokes shear on the pressure gradient (see *Suzuki and Fox-Kemper, 2016*) is not taken into
 147 account. Note that only surface Stokes drift fields are sent by the wave model to the ocean model along
 148 with the Stokes transport. These are then used to approximate vertical Stokes profiles based on *Breivik*
 149 *et al. (2014)*.

150 In addition to these modifications in current equations, the boundary conditions are changed. The
 151 surface stress felt by the ocean is no longer τ_a but:

$$\tau_{\text{surf}} = \tau_a - \tau_{\text{aw}} + \tau_{\text{wo}} \quad (10)$$

152 where τ_{aw} corresponds to the amount of momentum used by wave formation and τ_{wo} to the breaking
 153 wave induced stress transferred to the ocean. These fields, provided by WW3, are derived from the input
 154 and dissipation source functions (*Tolman, 2014*). At the bottom boundary, the stress due to the waves is
 155 added to the bottom friction. It is computed from the bottom orbital velocities \mathbf{u}_{bw} and a wave friction
 156 factor following *Soulsby et al. (1993)*. For the wave friction factor the parameterisation of *Soulsby (1997)*
 157 (their Eq. 62a) is used.

158 Waves impact the advection of tracers which is done by the Lagrangian velocity. Thus, with waves
 159 Eq. (3) becomes:

$$\frac{\partial C}{\partial t} = - \left(\frac{\partial}{\partial x} [(\hat{u} + u_s) C] + \frac{\partial}{\partial y} [(\hat{v} + v_s) C] + \frac{\partial}{\partial z} [(\hat{w} + w_s) C] \right) + \frac{\partial}{\partial z} \left(K_C \frac{\partial C}{\partial z} \right) \quad (11)$$

160 Waves effects have also to be considered as impacting eddy viscosity and diffusion terms in Eqs. (8)
 161 and (11). This is achieved by modifying the surface boundary conditions of the turbulent closure equations
 162 and adding a new source terms within the bottom boundary layer. The TKE production term added to
 163 the right hand sides of Eqs. (4) and (5) is taken from *Walstra et al. (2000)*. For k , it stands as:

$$P_w^{\text{bot}}(z) = \frac{2\Phi_{\text{bbl}}}{\delta} \left(1 - \frac{d + \zeta - z}{\delta} \right) \quad \text{for } d + \zeta - z \leq \delta \quad (12)$$

164 where Φ_{bbl} is the wave energy dissipation due to bottom friction sent by WW3 to MARS3D and d the
 165 topography. The bottom wave boundary layer thickness δ is derived following *Grant and Madsen (1982)*

166 (their Eqs. 5 and 6) based on the wave friction factor. These depend on the bottom orbital velocities
 167 \mathbf{u}_{bw} and the mean wave period T_{m1} provided by WW3.

168 Thus Eqs. (4) and (5) become:

$$\frac{\partial k}{\partial t} = -\mathcal{L}(k) + \frac{\partial}{\partial z} \left(\nu_k \frac{\partial k}{\partial z} \right) + P + D - \varepsilon + P_w^{bot} \quad (13)$$

$$\frac{\partial \varepsilon}{\partial t} = \frac{\varepsilon}{k} (c_{\varepsilon 1} P + c_{\varepsilon 3} D - c_{\varepsilon 2} \varepsilon) + \frac{\partial}{\partial z} \left(\nu_\varepsilon \frac{\partial \varepsilon}{\partial z} \right) + \frac{\varepsilon}{k} c_{\varepsilon 1} P_w^{bot} \quad (14)$$

169 For these two equations, the Neuman-type boundary conditions taking the waves into account at the
 170 sea surface are given by:

$$\frac{\partial k}{\partial z} = \Phi_{oc} \quad (15)$$

$$\frac{\partial \varepsilon}{\partial z} = (c_\mu^0)^{\frac{3}{4}} \left[\frac{k^{\frac{3}{2}}}{\kappa (z' + z_0)^2} + (c_\mu^0)^{\frac{3}{4}} \frac{\frac{3}{2} \sigma_k \Phi_{oc}}{c_\mu \kappa^2 (z' + z_0)^2} \right] \quad (16)$$

171
 172 with $c_\mu=0.09$ (*Burchard, 2001*) and Φ_{oc} the wave to ocean energy flux provided by WW3 accounting for
 173 the injection of TKE from breaking waves. Similarly to τ_{wo} , Φ_{oc} is derived from the parameterisation
 174 chosen for the dissipation source function in WW3. Note that Φ_{oc} replaces $c_w u_*^3$ from the *Craig and*
 175 *Banner* (1994) model for the wave enhanced layer in the boundary conditions reported in *Burchard*
 176 (2002). Rather than considering the surface wave TKE contribution as a flux, it could be inputted as
 177 a vertically distributed (at the scale of the heights of breaking waves) production term similar to P_w^{bot} .
 178 Given the very high mixing there is very little difference between these approaches *Raschle et al.* (2013).

179 2.3. Case Study

180 A realistic case study was devised to evaluate the impact of waves on the Ushant tidal front under low to
 181 moderate winds. Given the relatively short period over which consistent wind and wave conditions prevail,
 182 the simulations were run only for a couple of days. This does not allow for a full tidal decomposition
 183 of the results. However, choosing a period in which waves propagate consistently in one direction allows
 184 straight forward contrasting of different wave-tide alignments. Models (MARS3D, WW3) were set-up to
 185 best represent the conditions measured during the FROMVAR (Front de Marée Variable) field campaign
 186 between the 02 and 04 September 2011. An anticyclonic circulation was present at the beginning of the
 187 campaign with very weak winds and calm seas. With the arrival of an atmospheric front around 1700
 188 UTC on 02 September, southwesterly winds gradually intensified to reach a local maximum of 14 m s^{-1} on

189 03 September around 1600 UTC. The coupled simulations were started on 02 September at 0600 UTC but
190 in the following analysis, model outputs are only considered starting at 1200 UTC, allowing for adequate
191 wave spin up from calm conditions.

192 2.4. Model Configurations

193 The models were run at high horizontal resolution (500 m for MARS3D and 1500 m for WW3) over a
194 domain spanning about 160 by 160 km² (Fig. 1) with hourly outputs. The model configurations chosen
195 are those used for operational purposes as part of the “Modelling and Analysis for Coastal Research”
196 (MARC) project (<https://marc.ifremer.fr>). A stand-alone MARS3D run (version V11.0_OAW01) was
197 spun up starting January 2011 using a Bay of Biscay configuration with a horizontal resolution of 2.5 km
198 similar to that used operationally for Prévimer (*Lazure et al.*, 2009) (precursor to the MARC project).
199 A fine resolution zoom (500 m) over the Iroise Sea was embedded into the regional grid and integrated
200 through 2-way AGRIF nesting (*Debreu et al.*, 2008). This zoom provided the initial and lateral boundary
201 conditions for the MARS3D simulations used in the present study. Run from 0600 UTC on 02 September
202 2011 to 0000 UTC on 04 September 2011, the stand-alone MARS3D simulation analysed herein gives
203 almost identical outputs to the zoom. The chosen model configuration and forcing were shown to best
204 reproduce the front. Choice of the turbulence scheme was motivated by previous model development
205 (*Bennis et al.*, 2011).

206 MARS3D was forced with tidal components taken from the global Finite Element Solution tide model
207 FES2004 (*Lyard et al.*, 2006) and atmospheric forcing fields consistent with those used to force the Bay of
208 Biscay run. These atmospheric forcing fields come from the operational French forecast model AROME
209 with a temporal resolution of 1 hour and a spatial resolution of 0.025° (~2.5 km). AROME provides the
210 following variables to MARS3D: 2-meter air temperature, atmospheric pressure, relative humidity, 10-m
211 zonal and meridional wind components, and cloud cover. Heat fluxes are internally computed based on
212 the NOMADS-2 parameterisation for solar fluxes proposed by *Gill* (1982), the “EDF” parameterisation
213 for thermal fluxes described in *Dumas and Langlois* (2009), and COARE 3.0 (*Fairall et al.*, 2003) for
214 the turbulent fluxes. MARS3D operates on an Arakawa C grid with topographically conformal vertical
215 coordinate (σ) system. The vertical resolution was set to 40 σ levels. Figure 3 shows the mean surface
216 (0-30 m) vertical resolution over a tidal cycle. The top sigma level is about 15 cm below the sea surface.
217 Each subsequent sigma level is about 30 cm deep over the top 2.4 m of the water column, then gradually
218 increase in thickness to be around 0.5 m at 5 m below the water line. Surface diagnostics of the current
219 and temperature equations shown in the results section are from the top sigma level while near surface

220 $k - \varepsilon$ diagnostics are from the top mid-level. The model automatically controls the timestep starting
221 from a maximum timestep of 20 s and a critical Courant-Friedrichs-Lewy (CFL) condition set to 0.6. The
222 QUICK (Kowalik and Murty, 1993) numerical scheme is used for the advection of currents. For tracer
223 (temperature and salinity) a fifth order upwind scheme is used for horizontal advection and an upwind
224 compact and conservative scheme is used for vertical advection (Debreu and Duhaut, 2011). These are
225 employed in a three dimensional two-step MACHO method (Leonard et al., 1996). An implicit scheme is
226 used for vertical diffusion of currents and tracers. The forcing, parameterisations, and numerical schemes
227 chosen correspond to those used in the bay of Biscay configuration which combined with the AGRIF
228 downscaling method allow for the best representation of the Ushant front.

229 In WW3 (adapted from v5.16), the spectral space was discretized using 32 frequencies ranging from
230 0.0373 to 0.7159 Hz in 10% steps ($f_{i+1} = 1.1f_i$, where i is a discrete grid counter and f the frequency)
231 with 24 directions ($\Delta\theta = 15^\circ$). The overall timestep was set to 100 s, the spatial (CFL without currents)
232 and spectral (refraction) propagation timesteps to 25 s, and the integration of the source function to 10 s.
233 The physics package used is ST3 which prescribes an f^{-5} spectral tail outside the model frequency range
234 (Bidlot et al., 2005; Tolman et al., 2014). This set of source function parameterizations was chosen for
235 their ability to reproduce the variability in the drag coefficient. For a review of the performances of the
236 different physics packages available see Stopa et al. (2016). The model was started from calm conditions
237 ($H_s=0$) and forced at the boundaries by 3 hourly energy spectra produced by the HOMERE reanalysis
238 (Bouidière et al., 2013) at the open boundaries. The atmospheric forcing for WW3 (zonal and meridional
239 components of the 10m wind) are taken from the AROME fields used to force MARS3D.

240 3. Results

241 The wave impact onto the ocean is analysed by contrasting results of the coupled MARS3D-WW3 run
242 with those of the stand-alone MARS3D run. The following paragraphs focus on the northern extension
243 of the front around a longitudinal transect at 48.8°N as well as the two nearly homogeneous areas Z1 and
244 Z2 located on each side of the Ushant front (see Fig. 1) where the water depth is 116.2 ± 0.97 m and 98
245 ± 2.2 m, respectively.

246 3.1. Environmental Conditions Simulated

247 Figure 4 shows time series of the key variables describing the environmental conditions over the
248 simulated period. Average conditions are plotted for the whole domain (black curves) as well as for two

249 equal sized zones, one on either side of the front: Z1 (stratified, red curve) and Z2 (well mixed, blue
250 curve); c.f. Figure 1. As shown below, the tidal signal of the current (rather than the sea level) is central
251 to understand the impact of waves on the front. Throughout the paper, particular attention will be
252 drawn to the relative alignment between current and wave propagation directions. Therefore, periods
253 when waves propagate with (against) the tide roughly corresponding to flood (ebb) or northeastwards
254 (southwestwards) flow are highlighted with coral (blue) shadings on the figures.

255 The mean winds grow gradually from ~ 3 to ~ 8 m s^{-1} between 1200 UTC on 02 September and 1800
256 UTC on 03 September before decreasing shortly until 2100 UTC and increasing again up to ~ 9 m s^{-1} at
257 the end of the simulation (Fig. 4c). A similar pattern is observed in Z1 and Z2, though winds reach a
258 maximum on 03 September of 9.6 m s^{-1} at 1300 UTC in Z1 and of 8.4 m s^{-1} at 1800 UTC in Z2. Also,
259 unlike in Z1 or when averaged over the whole domain, winds in Z2 do not increase again after 2100 UTC
260 on 03 September. They blow to the north-northeast throughout the majority of the simulation but for
261 the first and last few hours when average directions display more variability (Fig. 4d).

262 The tidal cycle as described by the sea level (Fig. 4a), current intensity (Fig. 4e), and direction (Fig.
263 4f) is semi-diurnal. Three tidal cycles with a tidal range of about 6 m are resolved over the study period
264 starting at low water. The magnitude of the tidal current (Fig. 4e) varies between ~ 0.4 and ~ 0.8 m s^{-1}
265 s^{-1} on average over the whole domain and Z1. This range is intensified near the coast as shown by the
266 temporal averages in Z2 that vary between ~ 0.2 and ~ 1.2 m s^{-1} . Currents are the strongest around times
267 of high and low water as is the case for progressive tidal waves.

268 From 2000 UTC on 02 September, the significant wave height increases from < 1 m to ~ 2 m (Fig. 4b)
269 and its temporal evolution follows that of the wind (Fig. 4c). The main spectral wave peak corresponds to
270 a swell system (see wave periods in Fig. 4b). Waves propagate to the northeast (Fig. 4h) and are roughly
271 aligned with the wind (Fig. 4d). The intensity of the Stokes drift (Fig. 4g) increases as the wind and the
272 waves grow. The wave period is seen to decrease smoothly over time. It does not appear to be influenced
273 by the tide. However, the Stokes drift presents two maxima 0.053-0.076 m s^{-1} and 0.073-0.1 m s^{-1} around
274 0200 and 1300 UTC on 03 September, respectively. The Stokes drift appears to be intensified during
275 ebb flow when waves roughly oppose the tidal current (blue shaded periods). The significant wave height
276 also displays local maxima around these times. A decrease in the Stokes drift and in the significant wave
277 height is observed during the two last flood tides of the study period. This aligns with the concept that a
278 wave-opposing current steepens (decrease in mean wavelength, increase in amplitude). A wave-opposing
279 current compresses the wave field while a wave-following current stretches, thus flattens it (*Ardhuin et al.*,
280 2017; *Phillips*, 1984). As the Stokes drift is proportional to the square of the steepness of the waves it

281 increases.

282 *3.2. Frontal Displacement and the Temperature Equation*

283 The sea surface temperature (SST) front is well represented in both MARS3D runs. It is characterized
284 by a strong SST gradient between 4.9°W and 5.1°W with warm ($\text{SST} > 15.5^{\circ}\text{C}$) stratified waters offshore
285 and cold ($\text{SST} < 14^{\circ}\text{C}$) well mixed waters close to the coast (Fig. 1a). The mixed layer whose depth is
286 computed based on a temperature criterion of 0.2°C absolute difference from surface, is around 10-20 m
287 deep on the stratified side and reaches the sea floor on the mixed side (Fig. 1b). Note that computing
288 the mixed layer depth based on a density criterion does not significantly alter the results. Looking
289 at longitude-time Hovmöller diagrams of the SST along the transect at 48.8°N clearly shows the zonal
290 displacement of the Ushant front with the tidal flow (Fig. 5b). As expected, it is seen to advance towards
291 the shore with the flood and retreat offshore with the ebb flow in both the stand-alone and coupled
292 simulations as illustrated in Figure 5b. The zonal displacement at 48.8°N is not in phase with the mean
293 sea level (MSL, Fig. 5a) but rather with the zonal surface current (Fig. 5d) showing how tidal advection
294 drives the front's position.

295 A surface negative temperature anomaly of up to $\sim 1.5^{\circ}\text{C}$ in the stratified side (Fig. 5c) is visible in
296 the coupled run compared to the stand-alone run. This cooling is pronounced ($>1^{\circ}\text{C}$) within 2 to 4 km
297 west of the front location in the stand-alone MARS3D run between 0100 and 1800 UTC on 03 September
298 but extends over 10 kilometers further. The differences in temperature and displacement intensify during
299 the simulated period as the waves grow. No clear link is observed between the intensity of the SST
300 response and the tidal cycle. A wave induced cooling can be expected due to wave surface breaking
301 induced mixing (Eqs. 15, 16) which would only have visible impacts on the temperature on the stratified
302 part. However, the analysis of the location of the maximum SST gradient along 48.8°N reveals that this
303 cooling is associated with a westward displacement of the Ushant front. Differences in the surface tracer
304 advecting velocities between the coupled and stand-alone runs are mostly negative around the position of
305 the front (Fig. 5e). This indicates a reduction of the eastward advection and an increase of the westward
306 advection. On the mixed side of the front, the differences are positive indicating an increased advection
307 to the east in line with the Stokes' drift and regardless of tidal phase. On the stratified side of the
308 front, changes in tracer advection are more variable with both positive and negative regions and periods
309 without a clear relation to the tidal phase. The mixed layer depth is seen to reach the sea bottom within
310 a few kilometers west of the SST front as detected in the uncoupled run further hinting at the westward
311 displacement of the front due to waves (Fig. 5f). A deepening of the mixed layer of 5-10 m is also seen

312 throughout the stratified side outside of the frontal region. It intensifies over time and with proximity to
313 the front.

314 The location of the SST front is obtained based on the maximum values of the SST gradient or mixed
315 layer depth (MLD) obtained by a Sobel filter (*Pringle, 1969*). Its temporal evolution at 48.8°N is shown
316 in Figure 6a. Both types of estimation are consistent between them. The one based on the MLD gives
317 a more regular forehead position that clearly follows the tidal flows. The SST based one appears noisier.
318 When wave-current interactions (coupled run) are modeled, the position deduced from the SST gradient is
319 up to 4 km further west than in the stand-alone run (Fig. 6b). Tracking a specific isotherm such as 14.7°C
320 gives comparable results (not shown). The offset of the position deduced from the maximum gradient
321 of MLD deduced from the coupled and stand-alone runs reaches 3.5 km at the end of the simulation,
322 tracking the SST offset (Fig. 6b). Although results are shown for a specific latitude, the impact of waves
323 is clearly visible all along the Ushant front. As illustrated in Figure 7, the front has similar meanders
324 in the stand-alone (panel a) and coupled (panel b) runs. Mapping the difference in SST between the
325 coupled and the stand-alone run (Fig. 7c) clearly reveals cooling on the stratified side of the front. Some
326 positive differences in SST are visible in the southern extension of the front where meanders are stronger,
327 particularly near the Ushant Island. Presence of the island and shallow bathymetry there complicates the
328 dynamics and wave interactions.

329 Positive salinity and density anomalies accompany the negative surface temperature anomaly on the
330 west side of the front (Fig. 8). The anomalies extend to the MLD on the stratified side of the front
331 without any clear variation of magnitude with depth. Up to ~5 m beneath the MLD of the stand-alone
332 run, the anomalies are of opposite sign as can be expected from enhanced mixing. This is accompanied
333 with a deepening of the MLD of ~2-3 m. No significant differences in temperature and salinity, hence
334 neither in density, are found at depth between the run with or without waves (a full depth version of
335 Figure 8 can be found in Supplementary Materials, c.f. S1). This suggests that only the surface front is
336 impacted by waves under the forcing considered here. The waves impact on the tracer fields is however
337 clearly seen several meters below the mixed layer.

338 Three physical processes could explain the SST cooling and the westward shift of the SST front in the
339 coupled MARS3D-WW3 compared to the stand-alone MARS3D run:

- 340 1. horizontal advection of SST gradient to the west replacing warm stratified waters by cold waters
341 from the mixed side of the front;
- 342 2. increase of the vertical mixing through additional injection of TKE in ocean due to the presence of
343 waves;

344 3. changes in vertical entrainment at the MLD bottom bringing cold water up due to wave induced
345 changes in mean vertical velocities.

346 Changes of vertical entrainment as computed from the vertical velocity using the continuity equation
347 are not significant. The leading order processes driving the temperature evolution are advection and
348 vertical diffusion. Contrasting the budget of the temperature equation of the coupled and stand-alone
349 runs (Eqs. 3 and 11, respectively) allows to determine which of these two processes changes more in
350 response to wave coupling. Figure 9 shows Hovmöller plots at 48.8°N of the different terms of the
351 temperature equation for the stand-alone MARS3D run (panels a and b) and the difference between the
352 coupled wave-ocean and the stand-alone MARS3D runs (panels c to e). The temporal trend term of the
353 stand-alone run is not shown because it is very closed to the total advection term as expected in a tidally
354 dominated environment. Note also that budget terms are hourly averaged rather than instantaneous as
355 in previous figures. The semi diurnal tidal signal is clearly visible in the total advection (Fig. 9a) but not
356 in the vertical diffusion term (Fig. 9b) which is negative on the well mixed side of the front and positive
357 on the stratified side. The plots of differences reveal that the changes in the advective terms (Fig. 9d)
358 are larger around the front than the changes in the vertical diffusion (Fig. 9e). Indeed, the difference
359 in the temperature trend (Fig. 9c) follows that of the total advection revealing cooling near the front,
360 particularly during flood tide. Figure 9e does however clearly show an increase in vertical diffusion on
361 the warm side of the front at times.

362 3.3. Current and $k - \varepsilon$ Equations

363 To further explore the dynamics and energetics responsible for the wave induced changes described
364 above, current and $k - \varepsilon$ equation budgets computed from the coupled and stand-alone runs are compared.
365 Figures 10a,b,d, and e show vertical profiles of the horizontal components of the Eulerian and quasi-
366 Eulerian velocities averaged in Z1 (red) and Z2 (blue) for two instants: one when waves and currents
367 are opposed (1200 UTC on 03 September, top row) and one when they follow each other (1800 UTC on
368 03 September, bottom row). The general behaviour on both the stratified (Z1) and mixed (Z2) sides of
369 the front is similar. Currents opposing (following) to wave propagation are found to increase (decrease).
370 The vertical profiles all clearly feature a near surface gradient, although the mean flow is driven largely
371 by barotropic tides. The impact of waves on currents is clearly enhanced near surface but reaches below
372 the MLD which is around 15.3 m and 15.8 m at 1200 UTC and 13.8 m and 14.1 m at 1800 UTC in Z1
373 in the stand-alone and coupled run, respectively. The vertical eddy viscosities (Fig. 10c and f) are seen
374 to increase within the top ~10-15 m of the water column in both cases on either side of the front. The

375 increased mixing leading to reduced vertical gradients can explain the increased (decreased) quasi-Eulerian
 376 velocities in condition of wave-opposing (-following) currents. A positive vertical gradient (shear), likely
 377 due to Ekman dynamics, exists at all times in both the zonal and the meridional velocity components.
 378 The resulting down-gradient turbulent diffusion leads to an increase in magnitude of the upper ocean
 379 velocity when negative and a decrease in the magnitude when positive.

380 The impact of waves on the magnitude of the near-surface tidal current is further analysed through
 381 time series of differences between the magnitude of the quasi-Eulerian current in the coupled run and
 382 that of the Eulerian current in the stand-alone run (Fig. 11a). The differences of the current magnitudes
 383 averaged over Z1 reach $0.080 \pm 0.007 \text{ m s}^{-1}$ during the ebb flow on 03 September at 1200 UTC and -
 384 $0.073 \pm 0.010 \text{ m s}^{-1}$ during the rising tide at 1800 UTC on 03 September. This equates to changes in the
 385 (quasi-)Eulerian surface current magnitude of up to $\pm 17.5\%$ relative to the Eulerian current magnitude of
 386 the stand-alone run in Z1. Changes on the mixed side of the front (Z2) are relatively smaller, amounting
 387 to $+11\%$ and -16.7% . The differences in the zonal (meridional)(quasi-)Eulerian current components
 388 (see Supplementary Material S2 and S3) are for the most part negative indicating that east(north)ward
 389 flows are reduced and west(south)ward flows are enhanced. Note that the magnitude of the differences in
 390 (quasi-)Eulerian currents is for the most part smaller than the magnitude of the Stokes drift (see Fig. 4g).
 391 Indeed, comparing the Lagrangian velocity of the coupled run to the Eulerian velocity of the stand-alone
 392 run suggests the Stokes drift tends to compensate the changes in (quasi-)Eulerian currents. It increases
 393 (decreases) the wave-following (-opposing) currents by $<3\%$ outside of the frontal region, accounting for
 394 the positive $\Delta|\mathbf{u}_L|$ on the well mixed side in Figure 5e. However, as shown in Figure 5e, this is not the case
 395 in close proximity of the temperature front where the Lagrangian velocity in the coupled run is smaller
 396 than the Eulerian velocity of the stand-alone run during flood tides and larger during ebb flow.

397 The analysis of the current equation budget allows to evaluate the main physical balances at play.
 398 Given the budget of zonal and meridional currents, it is easy to derive that of the current magnitude.
 399 The evolution of the horizontal current follows from Eqs. (1) and (8):

$$\frac{\partial \sqrt{u^2 + v^2}}{\partial t} = \frac{1}{\sqrt{u^2 + v^2}} \left(u \frac{\partial u}{\partial t} + v \frac{\partial v}{\partial t} \right) \quad (17)$$

400 Note that doing so eliminates the (quasi-)Eulerian Coriolis terms, meaning that the temporal evolution
 401 of the current magnitude follows the pressure gradient term at first order (Fig. 11b). Plotting the terms
 402 of the equations for the zonal and meridional components (see Supplementary Material S2 and S3) rather
 403 than the module clearly shows that the main evolution of the currents is driven from a balance between
 404 the pressure gradient and the Coriolis force, i.e. tides. Figure 11b shows the time series of the domain

405 averaged terms contributing to the evolution of current magnitude. Starting around 2000 UTC on 02
 406 September a separation is visible between the terms of the stand-alone (solid curves) and the coupled
 407 (dashed curves) MARS3D outputs in both the temporal trend (black curves), the pressure terms (purple
 408 curves), and the vertical diffusion term (light blue curves). Note that the addition of the wave induced
 409 pressure (J) does not significantly alter the pressure gradient terms. The observed offset between the
 410 solid and dashed purple curves reflects differences between the Eulerian current of the stand-alone run
 411 and the quasi-Eulerian current of the coupled run. When looking at the zonal and meridional components
 412 (Supplementary Material S2 and S3), the change in (quasi-)Eulerian currents is reflected in the (quasi-
 413)Eulerian Coriolis terms ($if\mathbf{u}$). Time series of the difference between the coupled and the stand-alone
 414 MARS3D fields (Fig. 11c) clearly show that as the waves start to grow the Stokes-Coriolis term grows.
 415 The difference in trend of the quasi-Eulerian velocity in the coupled run and the Eulerian velocity in the
 416 stand-alone run arises from changes in the vertical diffusion term and the Coriolis terms which evolve
 417 in opposite phase. The balance described above was verified to hold in average not only over the whole
 418 domain, but also in Z1 and Z2.

419 Changes in the vertical diffusion term arise from changes in the surface stress, the vertical shear, and
 420 the eddy viscosity (see Eqs. 1 and 8). The surface stress acting upon the ocean (Eq. 10 vs. Eq. 2) is
 421 reduced when waves and currents are aligned, but enhanced when opposed, with changes of the order of
 422 $\pm 10\%$ relative to τ_a . The near surface shear is reduced regardless of wave-current alignment. The near
 423 surface eddy viscosity is enhanced on average by a factor of $\mathcal{O}(10)$ in the coupled run compared to the
 424 stand-alone run due to changes in the $k - \varepsilon$ equations (Eqs. 12-16 vs. Eqs. 4-7). As discussed in Section
 425 2.2, the surface boundary conditions are modified when wave effects as derived from WW3 model are
 426 taken in account. Consequently, the near surface TKE (Fig. 12a) and the dissipation ε (not shown) are
 427 seen to increase as the waves grow displaying two maxima similar to the Stokes drift magnitude and H_s .

428 As variations of the TKE dissipation rate largely reflect those of TKE, more insights may be gained
 429 by looking at the evolution of the dissipation length scale L derived via the *Taylor* (1935) scaling:

$$L = C_L \frac{k^{3/2}}{\varepsilon} \quad (18)$$

430 where the proportionality constant $C_L = (c_\mu^0)^{\frac{3}{4}} \simeq 0.146$ is derived from the stability function c_μ for $D =$
 431 0 and $P = \varepsilon$ (see *Burchard, 2002*). While the near surface L in the stand-alone run is nearly constant
 432 and equal to 0.24 ± 0.031 m, it increases from 0.23 to 0.48 m when averaged over the whole domain in
 433 the coupled run (Fig. 12b), mimicking the evolution of the H_s and the Stokes drift. Note that L in the
 434 stand-alone run is directly proportional to z_0 which was set to 0.4 m. This is equivalent to conditions
 435 with H_s equal to 0.67 m ($z_0 = 0.6H_s$, following the scaling law proposed by *Terray et al. (1996)* with the

436 proportionality coefficient of *Soloviev and Lukas* (2003)) which roughly corresponds to the wave heights
 437 at the beginning of the coupled simulation. Note that other scalings of z_0 as a function of H_s can be
 438 found in the literature (*Raschle et al.*, 2006), particularly $z_0 = 1.6H_s$ (*Terray et al.*, 2000) which unlike
 439 the scaling proposed by *Soloviev and Lukas* (2003) includes the contribution of swell. Taking $z_0 = 1.6H_s$
 440 increases mixing in the coupled run leading to an unrealistically flat temperature front at the end of the
 441 2.5 days simulation. It does however have no substantial impact on the stand-alone run. As z_0 appear
 442 in the denominator of the surface boundary condition for ε (Eq. 16), increasing it leads to a reduction
 443 in ε and thus an increase in k and L . This in turn further increases the diffusivities, leading to a further
 444 deepening of the mixed layer and cooling of the surface.

445 The leading order terms of the near surface TKE budget in both the stand-alone and coupled runs
 446 are the vertical diffusion and the TKE dissipation rate (Fig. 13b). These are substantially enhanced
 447 in the coupled run. The vertical diffusion term displays a clear tidal variation in the stand-alone run
 448 (not shown), varying with current magnitude, being minimum (maximum) an hour before the current
 449 maximum (minimum). The tidal signature in the vertical diffusion term is no longer visible in the
 450 coupled run. Rather, like the TKE dissipation rate, it increases as the waves growth and the two periods
 451 of enhancement are clearly seen in the domain mean time series. The shear production term is seen to be
 452 dampened by waves in the near surface k equation (Fig. 13a) as expected from the increased mixing.

453 3.4. Analysis of Partially Coupled Runs

454 In order to better identify the different processes at play, a series of partially coupled model experiments
 455 were run. Four partially coupled runs are considered in this section: a run in which all Stokes drift related
 456 processes are included in the current and tracer equations (STOKESALLonly), a run where only the Stokes
 457 advection terms are included in the tracer equations (STOKESADVonly), a run where only the Stokes-
 458 Coriolis terms are included in the current equations (STOKESCORonly), and a run where waves are
 459 only taken into account in the turbulence closure model (WAVETURBonly). For the first three partially
 460 coupled runs, the turbulence equations and surface boundary conditions remain unchanged, i.e. there is
 461 no increase in K_u or K_C and the vertical diffusion terms are the same as in the stand-alone MARS3D
 462 run. In all the above mentioned runs the vertical boundary condition of the current equations is that
 463 of the stand-alone run, i.e. the impact of the waves on the surface stress is ignored. Partially coupled
 464 runs where only the stress was changed (not shown) revealed that it does not alter the front position
 465 significantly.

466 Figure 14b shows the cross-front SST at 48.8°N for the partially coupled runs as well as the stand-alone

467 and the fully coupled runs. The SST curves are centered on the position of the 14.7°C isotherm in the
468 stand-alone run. This snapshot illustrates the relative frontal displacement between the runs once the wave
469 impact is visible. As expected, including only the Stokes advection terms (STOKESADVonly) leads to an
470 eastward shift of the front, in the direction of the wave propagation. Only including the Stokes-Coriolis
471 terms (STOKESCORonly) can have the opposite effect displacing the front westwards as shown for the
472 considered instant. The front remains however to the east of that in the fully coupled run. As mentioned
473 in the previous section, the Stokes-Vortex force has minimal impact: the run STOKESALLonly shows the
474 combined effect of the Stokes-Coriolis force on the current and of the Stokes advection on tracers. It leads
475 to a slight eastward displacement of the front relative to the stand-alone position. The Stokes-Coriolis
476 force can act to increase the eastward displacement along with the Stokes drift, depending on the relative
477 alignment between the currents and wave propagation. These partially coupled experiments suggest that
478 the wave induced mixing is largely responsible for the frontal displacement. Indeed, the frontal position
479 of the WAVETURBonly run follows that of the fully coupled run very closely and is at times even further
480 to the west than in the fully coupled run. Although results in Section 3.1 suggest that for temperature
481 wave induced changes in mixing are less important than wave induced changes in advection, this is not
482 the case for currents. Thus, it is the impact of wave mixing on currents rather than on temperature that
483 is the key process explaining the main difference between stand-alone and coupled runs.

484 Vertical profiles of the (quasi-)Eulerian and Lagrangian velocities along the front (Fig. 14) clearly
485 show strong baroclinicity on the stratified side of the front. Profiles of the zonal and meridional current
486 components display a positive vertical gradient which is more pronounced on the stratified side of the
487 front. Thus, when the flow is positive (negative)/north-eastwards (south-westwards) the flow is stronger
488 (weaker) on the stratified side of the front than on the mixed side. Consequentially, once the front is
489 displaced westwards due to mixing, the surface velocities within several kilometers of the front as identified
490 by the 14.7°C isotherm are homogenised: their intensities have increased when negative and decreased
491 when positive. This shift of regime induced by wave mixing within the frontal area has a greater impact
492 than the changes related to the Stokes drift.

493 **4. Discussion**

494 The realistic model simulations described above reveal the role of gravity waves in modifying the
495 position of a surface thermal tidal front. Waves propagating shore-ward roughly perpendicularly to the
496 front result in a displacement of the front in the opposite direction of the wave propagation and Stokes
497 drift. This is due to an increase (decrease) of the quasi-Eulerian currents when waves oppose (follow)

498 them which is more important than the Stokes drift around the front. The following paragraphs draw
499 parallels between these results and previous work before exposing avenues for future development and
500 discussing broader implications.

501 *4.1. Comparison to Laboratory Experiments*

502 The simulated quasi-Eulerian current response to waves is in line with early laboratory measurements
503 (*Bakker and Van Doorn, 1978; Kemp and Simons, 1982, 1983; Klopman, 1994, 1993; Umeyama, 2005*).
504 Full depth Eulerian-mean current records show an increase (reduction) in surface currents when opposed
505 (following) to waves compared to the classic logarithmic law of the wall current profiles without waves.
506 These flume experiments were geared mainly towards analysing how waves alter currents in the bottom
507 boundary for different bed roughness. Neertheless, they show systematic changes in the surface currents.
508 They are regularly considered as the “truth” for wave-current interaction model developments although
509 being based on paddle generated non-breaking wave trains which do not have the three dimensionality
510 and spectral spread comparable to real wave fields. It had been argued that the observed wave impact was
511 due to the presence of lateral boundaries which induce Langmuir circulations (*Dingemans et al., 1996*).
512 However, transverse circulations due to sidewalls were shown to only weakly impact velocity profiles
513 (*Groeneweg and Battjes, 2003*).

514 The mean velocity shear was also observed to be altered by waves in the aforementioned laboratory
515 records: it increased when waves propagated against the current and decreased or even changed sign when
516 waves and currents propagated in the same direction. Turbulent intensity measurements from *Umeyama*
517 (2005) suggest that changes in shear were due to the wave-current Reynolds stresses which arise from the
518 phase averaged correlation between the horizontal and vertical particle motion. The sign of the wave-
519 current Reynolds stress always opposes that of wave propagation. Thus, for wave-following (-opposing)
520 the current, it is of the opposite (same) sign to the current shear leading to a reduced (enhanced) shear.
521 Wave-current Reynolds stresses are not directly included. As it stands, the coupled framework presented
522 here leads to a reduction of the vertical velocity shear in the surface layer due to the increased wave
523 mixing regardless of the relative alignment between currents and waves. Yet the expected enhancement
524 of the quasi-Eulerian current is reproduced during wave-opposing periods. This is only because mixing
525 homogenises the positive background surface current gradient which exists regardless of waves under the
526 simulated wind conditions.

527 4.2. Comparison to Wave-Current Models and Boundary Layer Theories

528 Several analytical 1D wave-current models and boundary layer theories have been proposed to repro-
529 duce the quasi-Eulerian current response observed in the laboratory experiments detailed above. Relying
530 on either the surface distortion of the depth dependent eddy-viscosities (*Huang and Mei, 2003*), parame-
531 terization of wave induced second order stresses (*You, 1996*), or a mixing length hypothesis (*Yang et al.,*
532 2006) they are capable of roughly replicating measured vertical velocity profiles. More recently, *Olabarri-*
533 *eta et al.* (2010) proposed a 3D non hydrostatic Eulerian wave-current model using a one equation eddy
534 viscosity turbulence closure able to mimic the current response to waves from the laboratory experiments.
535 They used it to study different wave-current alignments for shallow to deep water waves. *Teles et al.*
536 (2013) used 3D Reynolds Averaged Navier-Stokes to evaluate how well three turbulent closure schemes
537 could reproduce the conditions measured in laboratory by *Umeyama (2005)* and *Klopman (1994)*. They
538 concluded that the two first order models ($k-\varepsilon$ and $k-w$) which rely on the eddy viscosity hypothesis do not
539 reproduce laboratory results as well as the Reynolds Stress transport Model (RSM). *Teles et al.* (2013)
540 however imposed a surface boundary condition to their first order models which forces the eddy viscosity
541 to decrease towards the surface. This is contrary to what is imposed in the realistic simulations presented
542 here where wave coupling leads to a surface enhancement of the eddy viscosity due to the input of wave
543 induced TKE.

544 A fundamental discrepancy between the current work and the laboratory experiments, the theoretical
545 work, and numerical studies discussed so far is in the relative magnitude of the currents and Stokes drift.
546 While in the present study the tidal currents are much faster than the waves, they are of the same order of
547 magnitude in the aforementioned studies. Furthermore, the current work focuses on deep water waves. By
548 contrast, the laboratory experiments, which the previous studies aim to reproduce, featured intermediate
549 depth waves with a ratio of wave height over depth of 0.24 and 0.1 respectively for *Klopman (1994)* and
550 *Umeyama (2005)*. Consequently only limited comparisons to previous laboratory and analytical works are
551 possible. Numerical development may be necessary to improve the dynamics and kinematics of surface
552 wave-current interactions but dedicated in situ surface current and turbulence profile measurements are
553 also needed for validation.

554 4.3. Comparison to Regional Coupled Modelling Studies

555 Previous realistic coupled modelling studies, which do not include an RSM, reported no substantial
556 impact of waves on currents. Closer inspection of published figures, however, reveals a wave induced
557 change in currents of about 10% in two of them which is of the same order as those reported herein.

558 These studies were conducted under much stronger wind conditions and weaker currents than those
559 simulated here: one during wind-jet events with wind induced currents (*Ràfols et al.*, 2019), the other in
560 a tidal estuary (*Osuna and Wolf*, 2005). Using the COAWST modelling system for the north Ebro shelf,
561 *Ràfols et al.* (2019) showed that the main impact of waves was on the water column stratification as waves
562 inject turbulent kinetic energy and enhance surface stress thus deepening the mixed layer. Their results
563 indicate differences in surface currents of up to 20 cm s^{-1} for currents ranging between 20 to less than 80
564 cm s^{-1} under winds from 10 to 20 m s^{-1} . *Osuna and Wolf* (2005) reported a daily mean differences of
565 up to 10 cm s^{-1} during a strong west-southwesterly wave event under winds of $15\text{-}20 \text{ m s}^{-1}$ in the shallow
566 coastal areas (with depth around 50 m) of the eastern Irish Sea where the current magnitude is around
567 1 m s^{-1} . This is based on output from the coupled Proudman Oceanographic Laboratory Coastal-Ocean
568 Modelling System-ProWAM framework. It is not possible to determine from the article how the observed
569 enhancement relates to the relative alignment between the tidal currents and the waves.

570 The wave related processes found to be important in the Iroise Sea numerical experiments presented
571 here are: the Stokes-Coriolis force which along with changes in vertical diffusion due to wave injection
572 of TKE and surface stress alter surface currents. In the Irish Sea estuary, only the wave induced surface
573 stress was reported to be key (*Osuna and Wolf*, 2005). Analysis of the cross-shelf momentum equation in
574 the Ebro simulations revealed a main balance between the pressure gradient and the Coriolis term before
575 wind events, although with wind speeds of 10 m s^{-1} , with all other terms being an order of magnitude
576 smaller (*Ràfols et al.*, 2019). During wind-jet events in the Ebro region, the vortex force, pressure gradient,
577 surface stress, and horizontal advection were found to be of the same order 4 km offshore, where the water
578 is about 50 m deep. Further offshore, up to tens of kilometers, the vortex force and surface stress were
579 shown to mostly balance the pressure gradient. In the macro tidal regime simulated in the Iroise Sea the
580 wave effect on the horizontal advection and pressure gradient are negligible and under low wind conditions,
581 the vortex force is found to be secondary to other wave processes. Its role in altering the currents and
582 front position under stronger winds has yet to be investigated.

583 *4.4. Comparison to Remotely Sensed Measurements*

584 The partially coupled simulations reveal that advecting the temperature with the Lagrangian velocity
585 without allowing feedbacks of wave mixing and the Stokes-Coriolis force leads to an eastward bias of the
586 frontal position. The erosion of the temperature front associated with the wave mixing is also shown to
587 be key and explains the westward shift of the front. Joint analysis of hourly satellite derived SST and
588 HF radar derived currents at 48.75°N suggested that the Ushant front is not advected by the Stokes drift

589 (*Chevallier et al.*, 2014). Estimating the front position from advection based on HF radar derived currents
590 during a period of moderate easterly winds ($5-10 \text{ m s}^{-1}$) led to a westward bias of tens of kilometers after a
591 couple of days. A closer to real estimate of the temporal evolution of the front position by advection was
592 only possible after removal of the Stokes bias (*Ardhuin et al.*, 2009) from the current measurements. A
593 small westward bias is still visible after the Stokes drift correction which may hint to the fact that it does
594 not take into account the impact of surface gravity waves on the quasi-Eulerian currents. The present
595 study suggests that for a more complete correction of the Stokes drift effect in HF radar measurements,
596 the knowledge of the vertical gradients of the horizontal velocity is necessary as well as an estimate
597 of the wave induced mixing. While the finding of *Chevallier et al.* (2014) may suggest that the surface
598 temperature should be advected by the quasi-Eulerian velocity only, the authors ignore the impact of local
599 tidally induced adiabatic mixing which maintains the frontal dynamics. As the tidal residual current in
600 the region is to the north-east, pure advection would lead to an eastward drift of the front which overtime
601 would end up on the coast. This is clearly not observed. The HF radar measurements give the currents
602 within the top tens of centimeters of the water column while the surface frontal signature results from
603 the dynamics of the top tens of meters. Advecting the front by Lagrangian HF radar observations thus
604 overestimates the relative importance of the Stokes drift compared to other wave impacts (mixing) and
605 leads to a front displacement disconnected from mixed layer dynamics.

606 4.5. Limitations and Avenues to Improve the Coupled Framework

607 The impacts of TKE production by Stokes drift and Langmuir turbulence were not included in the
608 present study nor the previously mentioned coastal coupled modeling efforts. As the current horizontal
609 resolution is too coarse to resolve Langmuir circulations (100 m - 1 km) a parameterization would need
610 to be included in the energy equations to take them into account. Several approaches can be envisioned
611 based on previous studies (e.g. *Kantha and Clayson*, 2004; *Harcourt*, 2013). Langmuir turbulence has the
612 potential to impact the water column deeper than wave breaking. Thus including it could lead to erosion
613 of the temperature stratification on the offshore side of the front, further contribution to a offshore
614 shift in its location. Another avenue for improving the current framework is to lift the hydrostatic
615 constraint or to include the effects of the Stokes shear force on the pressure term (see *Suzuki and Fox-*
616 *Kemper*, 2016). A higher vertical resolution would also be needed to properly resolve the Stokes shear.
617 As it stands, using the *Breivik et al.* (2014) parameterization for the vertical Stokes drift profiles, the
618 surface Stokes shear is underestimated. In the current framework, the surface current fed to the wave
619 model is that of the top vertical mode. In situations of strong surface current shear it may be more
620 appropriate to consider a vertically integrated current (*Suzuki*, 2019). The integration depth considered

621 could further be wavelength dependent. This however would add considerable computations. Improving
622 this parameterization, increasing the resolution, and applying the quasi-hydrostatic approach (*Suzuki*
623 *and Fox-Kemper, 2016*) would increase the impact of the Stokes vortex force. Many uncertainties still
624 surround the other parameterizations on which the framework relies. These include the source functions
625 of the wave model which are used to derive the surface stress felt by the ocean (τ_{surf}) and wave to ocean
626 energy flux (Φ_{oc}) as well as the boundary conditions of the turbulence closure scheme.

627 *4.6. Broader Implications*

628 The frontal displacement reaches up to 4 km within 1.5 days as waves propagating into the region
629 grow. Under steady wave forcing one can expect the front to shift until a new equilibrium is reached
630 and wave breaking induced mixing has eroded the surface velocity and temperature gradients. Frontal
631 displacements can be observed repeatedly over periods of a couple of days in a 14 day run with realistic
632 forcing. Note that for the conditions simulated in the present study, low wind and tidal dominated
633 dynamics, the two-way coupling between ocean and waves does not give significantly different results
634 than when forcing the ocean by wave model fields as long as tidal currents were used to produce the wave
635 fields. This was tested by running the coupled framework allowing only wave fields from a stand-alone
636 WW3 run to be sent to the ocean model hourly. Indeed, in the studied situation, the described changes in
637 the (quasi-)Eulerian currents are too small to significantly alter the properties of the swell. Thus, in this
638 particular case coupling is not necessary for either the wave or the ocean components. This may however
639 not be the case in non tidally dominated environments where currents are weaker or under stronger winds
640 or under short fetches as wind-seas are more sensitive to currents.

641 **5. Conclusions**

642 The current study shows how surface gravity waves alter the location of a surface tidal temperature
643 front. In accordance to previous theoretical and laboratory works, the coupled modelling framework
644 reproduces a reduction (increase) of the surface quasi-Eulerian currents when they follow (oppose) waves.
645 In a situation of mainly eastward propagating waves as in the present case study, the front is advected
646 westwards by up to 4 km due to a reduction in the flooding tide and an increase in the ebb flow. This
647 counter-intuitive impact opposes and over compensates the advection effect of Stokes drift around the
648 front. Note that the situation studied here is not strongly forced by winds and tidal currents are much
649 stronger than the wave induced drift. Yet the impact of waves is clearly detectable. The processes at play

650 are summarized in the diagram in Figure 15. Here horizontal ocean and wave variability on either side of
651 the front are neglected as the resolution is not yet sufficient to properly reproduce them. In the current
652 coupled framework, the main wave dynamics behind the changes in currents are the vertical mixing and
653 the Stokes-Coriolis force which leads to a transport that opposes the Stokes drift. Including wave physics
654 is seen to increase the vertical mixing at the sea surface due to the TKE injection related to wave breaking.
655 This increase in vertical mixing results in a reduction of the surface vertical gradient of the current which
656 is positive for both flood and ebb tides leading to the observed changes in quasi-Eulerian currents. Within
657 the studied environmental setting (strong tidal currents, moderate waves and winds) it appears that only
658 forcing the turbulence closure with a surface wave breaking energy flux is sufficient to reproduce the wave
659 impact produced by the fully coupled framework. In environments which are much more sensitive to
660 the local wind conditions such as upwelling systems or under extreme conditions feedback between the
661 ocean and the waves will have to be taken into account. Before a definite conclusion can be reached on
662 which coupling aspects are necessary for operational use in coastal seas, the coupled model framework
663 will have to be improved further. Both the horizontal and vertical resolutions need to be increased and
664 further development is needed to improve the representation of the Stokes shear and Stokes vortex force
665 and include Langmuir turbulence. Nevertheless, the present study highlights the importance of taking
666 wave-current interactions into account even in environments where the background flow is an order of
667 magnitude stronger than the Stokes drift. Thus, waves should be considered in dispersion studies even in
668 tidally forced coastal seas. The enhanced surface mixing resulting of injection of TKE from wave breaking
669 can significantly vertically homogenize surface tidal currents even under moderate winds. In altering the
670 surface advection, waves can lead to displacements of fronts. Valid in a tidally forced environment, the
671 processes described herein are likely more important where surface currents are weaker. Susceptible to
672 influence the position of any surface temperature front, wave-current interactions could be important in
673 dictating the offshore extent of upwelling systems. The coupled model framework exploited herein would
674 allow studying coupling dynamics and energetics in a wide variety of coastal settings through analysis not
675 only of state variables but also of the terms of the temperature, current, and energy equations.
