1 SUPPLEMENTAL INFORMATION

2
3
4 This document complements the review article. It provides detailed legends for Figures 1, 2 and
5 4, and a few additional comments to the main text. Annex 1 shows data for the determination
6 of biogenic silica (bSi) production measured by isotopic techniques.

7 8 **Section 1. Introduction**

9 **Detailed legend of Fig. 1 and flux abbreviations**

10 Schematic view of the Si cycle in the modern world ocean (input, output, and biological Si
11 fluxes), and possible balance (total Si inputs = total Si outputs = 15.6 Tmol-Si yr⁻¹) that is in
12 reasonable agreement with the individual range of each flux (F), see Tables 1 and 2. All fluxes
13 are in Tmol-Si yr⁻¹.

14 *-Inputs:* Rivers: $F_{R(dSi+aSi)} = 8.1$; Aeolian inputs: $F_A = 0.5$; Glacial meltwater: $F_{ISMW} = 0.3$;
15 Submarine groundwater: $F_{GW} = 3.1$; Dissolution of minerals: $F_W = 1.9$; Hydrothermal: $F_H =$
16 1.7

17 *-Outputs:* Burial: $F_{B(\text{net deposit})} = 9.2$; Sponges: $F_{SP} = 1.7$; Reverse weathering: $F_{RW} = 4.7$.

18 *-Biological and other fluxes:* Uptake (pelagic production) = $F_{P(\text{gross})} = 255$; Recycling (surface)
19 $F_{D(\text{surface})} = 143$ (D: P = 0.56 according to Tréguer and De La Rocha 2013); Export: $F_E = 112$;
20 Recycling (deep) $F_{D(\text{deep})} = 28$ ($F_{D(\text{deep})}/F_E=0.25$ according to Tréguer and De La Rocha 2013);
21 Rain = $F_{S(\text{rain})} = 84.0$; Recycling (sediment-water interface) $F_{D(\text{benthic})} = 74.8$; upwelling,
22 diffusion: $F_{\text{upw/ed}} = 102.8$.

23 *Flux abbreviations:* *dSi input fluxes:* F_R total river net discharge, F_A dissolution of aeolian -
24 transported siliceous dusts, F_{GW} submarine groundwater discharge, F_W dissolution of siliceous
25 material transported from land on the continental margins, and of basalt, F_H hydrothermal activity
26 of the oceanic ridges (axis + off axis), F_{ISMW} ice shelf melt water flux (subglacial melt water +
27 basal melting of ice shelves + melting of icebergs).

28 *Si output fluxes:* $F_{B(\text{net deposit})}$ long-term burial of biogenic silica, F_{SP} siliceous sponges, F_{RW}
29 reverse weathering by formation of authigenic silicate minerals.

30 *Biological fluxes:* $F_{P(\text{gross})}$ production of biogenic silica due to diatoms and other pelagic
31 silicifiers, $F_{E(\text{export})}$ export flux of biogenic silica to the deep reservoir, $F_{S(\text{rain})}$ part of the export
32 flux that reaches the sediment - water interface, $F_{B(\text{net deposit})}$ long-term accumulation of biogenic
33 opal in coastal and abyssal, sediments.

34 Note that the dSi uptake due to benthic organisms is not represented on Fig. 1. Indeed, the total
35 bSi production of benthic diatoms is presently unknown but it should be $< 5 \text{ Tmol-Si yr}^{-1}$
36 (Leynaert et al., work in progress), and that the total bSi production of sponges ($6.1 (\pm 5.9)$
37 Tmol-Si yr^{-1}) is still preliminary (Maldonado et al., work in progress).

38 *Other fluxes:* $F_{D(\text{surface})}$ recycling of Si by dissolution of the biogenic silica in the surface
39 reservoir, $F_{D(\text{deep})}$ part of the export flux that dissolves in the deep reservoir, $F_{\text{upw/ed}}$ transfer of
40 dSi from the deep to the surface reservoir by upwelling or eddy diffusion. $F_{D(\text{benthic})}$, flux at the
41 sediment - water interface, is according to Tréguer and De La Rocha 2013).

42

43 **Section 2 -The input fluxes**

44 **2.1 Detailed legend of Figure 2.**

45 Schematic view of the low temperature processes that control the dissolution of (either
46 amorphous or crystallized) siliceous minerals in seawater in the coastal zone and in the deep
47 ocean, feeding F_{GW} and F_{W} . These processes (white arrows) correspond to low or medium
48 energy flux dissipated per volume of a given siliceous particle in the coastal zone, in the
49 continental margins, and in the abysses, and to high kinetic energy flux dissipated in the surf
50 zone. Inputs of siliceous biogenic and lithogenic silica into the ocean are mainly due to
51 suspended matter transferred from the continent. Rivers support the main transfer of Si to the
52 coastal zone, either as dSi or as aSi. Abundant transfer of siliceous suspended matter into the
53 ocean is also expected from river mouths and deltas through dissemination of suspended matter
54 in the coastal zone, in the continental margin, and beyond to the abysses. In sandy and
55 permeable soil zones dSi is also transferred from the continent to the coastal zone through
56 submarine groundwater discharge processes either as net fresh water inputs or as
57 brackish/seawater recycling due to tidal pumping. In the surf zone, low temperature dissolution
58 of grains of lithogenic silica (quartz, feldspar, etc.) could be intense under the pressure of the
59 intensive and continuous shaking due to waves. For the sake of clarity, we distinguish the
60 processes at work in a quiet zone that receive river inputs from those occurring in a sand beach
61 zone subject to strong dissipation of energy due to wave motion. Note that neither the low-
62 temperature dissolution of wind-borne siliceous material (F_{A}) nor that occurring in high-
63 temperature hydrothermal systems (F_{H}) are represented on this figure.

64 **2.2 Dissolution of minerals**

65 Regarding the marine component of F_{W} dissolution of minerals, Fabre et al. (2019) (main text
66 reference list), focused on wave and tidal action prevailing in the intertidal surf zone (Fig. 2).
67 From laboratory experiment with pure quartz, they showed that quartz grains submitted to

68 violent agitation are capable of substantial dissolution of silica at time scale of days. According
69 to these authors, the flux of dissolution of siliceous material from sandy beaches is $F_{\text{dissolution}} =$
70 $k(T^{\circ}\text{C}) \times S_{\text{reactive}} \times (C^* - C_{\text{sw}})$. It corresponds to a net input of dSi to the ocean. In this equation,
71 $k(f(T^{\circ}\text{C}))$ in m s^{-1} is the mass transfer coefficient, S_{reactive} in m is the reactive surface of sand
72 grains, C^* in mol-Si L^{-1} is the temperature-dependent solubility limit of sand at thermodynamic
73 equilibrium, and C_{sw} , in mol-Si L^{-1} is the coastal seawater silicic acid concentration. Assuming
74 that all sandy beaches is composed of quartz, Fabre et al. (2019) calculated a global flux of 3.2
75 (± 1.0) Tmol Si yr^{-1} . However, this estimate is not well constrained.

76 Firstly, it is clear that the mineral composition of the world ocean beaches is not entirely
77 composed of quartz. Indeed, the composition of sandy beaches is variable and represent 31%
78 of the coastline of the continents at world scale (Luijendijk et al, 2018, main text reference list).
79 Sandy beaches are composed both of non-siliceous materials (mostly calcareous), and diverse
80 siliceous types of materials (amorphous silica, quartz, feldspars, clays, etc.). These siliceous
81 materials have different solubility and dissolution rates in seawater (S1: Lerman et al., 1975;
82 S2: Hurd et al., 1979), and they can be more or less coated by organic and metals, which affect
83 silica dissolution (e.g. S3: Loucaides et al. 2010; S4: Wiley, 1975). These differing sand
84 compositions directly affects the value of S_{reactive} as well as that of C^* .

85 Secondly, in surf zones the mixing conditions of sand and seawater can be very variable, both
86 over time and at local and regional scale, thus affecting the solid to liquid phase ratio, and the
87 values of the C^* .

88 Thirdly, Fabre et al (2019)'s value for C_{sw} (i.e. 85.4 μM), is far too high for coastal waters,
89 irrespective of its regional context in the world ocean.

90 Finally, C_{sw} can be seasonally variable, particularly in temperate zones.

91 Also note that, by definition, this flux is already included in the marine SGD estimate according
92 to Cho et al. (2018) (main text reference list)

101

102 **Section 3 -The output fluxes**

103 **Deposition of sponge silica in marine sediments**

104 The annual rate of sponge silica deposition to the sediments, unlike in diatoms, cannot be easily
105 calculated from annual production rates. The longevity of sponges, which ranges from months
106 or years to even centuries or millennia (S5: Elwood et al., 2007; S6: McMurray et al., 2008;
107 Jochum et al. 2017, see main text reference list), decouples the process of skeleton production
108 — which slowly accumulates bSi over the sponge lifespan — from the process of releasing the
109 accumulated bSi into the sediments — which occurs within weeks to months after sponge death.
110 The deposition of sponge bSi is also decoupled from the rain of planktonic, and therefore, from
111 the rate of sediment deposition. The reason of this is in the benthic nature of sponges. Sponges
112 live already attached to the bottom, so their bSi does no transit through the water column once
113 sponges die. While the organic components of the body become rapidly degraded (S7: Rützler
114 and McIntyre 1978), the mineral components (i.e. the siliceous skeletal pieces of sponges, called
115 spicules) do not. The skeletal pieces fall directly on the seafloor at the site where the sponge
116 was growing, forming a spicule patch (S8: Laguionie-Marchais et al., 2015), which can in some
117 cases persist for a long time (S9: Bett and Rice, 1992), being slowly disaggregated by the action
118 of scavengers and other benthic macrofauna (S10: Katz et al., 2016), also by the action of
119 bottom currents, turbidity currents included.

120 Once the spicules are delivered to the bottom, the period of time needed for them to be
121 buried and become accumulated bSi will mostly depend on the local rates of sediment
122 deposition, though also on the intensity of bioturbation (S10: Katz et al., 2016). In a study that
123 has considered sediments from a variety of marine environments ranging from shallow bays to
124 abyssal bottoms, the time required for the sponge spicules to reach the condition of permanently
125 buried bSi ranged from 471 to 74,074 years, depending on the depositional nature of the local
126 bottom (S11: Maldonado et al., 2019).

146

147 **Section 4 -The biological fluxes**

148 **4.1 Biogenic silica production as measured by isotopic techniques**

149 **Annex 1** shows all bSi production data with corresponding references.

150 **4.2 bSi pelagic production uncertainties**

151 The bSi pelagic production estimates from satellite NPP products, ocean biogeochemical
152 models, and empirical studies each have their own uncertainty. When NPP is extrapolated to
153 silica production, values are multiplied by estimates of the fraction of primary productivity done
154 by diatoms and then a Si:C ratio. Of these, the choice of a Si:C ratio for the HNLC regions is
155 the most uncertain. Our chosen value of 0.52 is 4 fold higher than for nutrient-replete temperate
156 diatoms (Brzezinski, 1985, see main text reference list), but field observations suggest
157 anywhere from no effect to an 8-fold increase (S12: Marchetti & Harrison, 2007, S13 :
158 Timmermans et al., 2004). Biases in satellite NPP models also contribute to uncertainties in
159 estimates of Si production. Particularly relevant are potential biases in Southern Ocean
160 chlorophyll concentrations (and consequently, NPP), which may be underestimated in the
161 Southern Ocean by as much as a factor of 3-4 (S14: Johnson et al., 2013).

162 For the biogeochemical models the two main sources of uncertainty are the extrapolation from
163 silica export to gross silica production using D:P ratios (Table 1 of Tréguer & De La Rocha,
164 2013, main text reference list), as well as uncertainties in the parametrization of Southern Ocean
165 physics and biology. For the seven GOBMs that report separate estimates of net silica
166 production for the Southern Ocean, when Southern Ocean silica production is regressed against
167 total global silica production the fitted line has an R^2 value of 0.96 with a slope equal to 1.05
168 (± 0.11). This points to model parameterizations of Southern Ocean physics and/or biology as
169 the major determinant of differences in global silica production estimates among GOBMs.

170 For the global bSi pelagic production estimates derived from field data, extrapolation over both
171 time and space is required. Few empirical studies of bSi production over an entire year are

172 available. The vast majority of annual estimates determined for Longhurst provinces are
173 extrapolated from field programs lasting a few weeks or less. Data sparsity remains a problem,
174 and in the analysis presented here some Longhurst zones contain only a single measurement
175 and nearly half of zones have no data at all (main text Fig. 3).

185 **4.3 bSi production: contribution of benthic diatoms**

186 Determination of bSi production by microphytobenthos is still in its infancy. However, we can
187 already foresee its potential impact in two ways. Through intensive studies in a temperate
188 subtidal ecosystem (S15: Ni Longphuirt et al. 2009, S16 : Leynaert et al. 2009, and S17 :
189 Chatterjee et al., 2013) we conservatively estimate that benthic diatoms can produce 1 mol-Si
190 m⁻² yr⁻¹. Extrapolation to the photic area of the world coastal ocean gives 6.8 Tmol-Si yr⁻¹.
191 Cahoon (1999) (S18) proposed a global estimate of annual benthic microalgal primary
192 production (based on the analysis of 85 worldwide studies) of 514×10^{12} gC yr⁻¹. Applying the
193 Brzezinski (1985) (main text reference list) mean Si/C molar ratio for marine diatom of 0.13 to
194 convert this carbon production in silica production, gives 5.4 Tmol-Si yr⁻¹. Both estimates are
195 in good agreement. Therefore, the biogenic silica production by the microphytobenthos might
196 represent about 2.5% of the global bSi production. It remains to be determined what proportion
197 of this flux will finally contributes to the net sink of bSi. Preliminary studies have shown that
198 bSi dissolution rates of benthic diatoms are 10 times slower than pelagic diatoms measured in
199 the same conditions.

210 **Section 5 – Discussion**

211 **5.1 Introduction to Fig. 4:** Depiction of a schematic Si cycle in the coastal and continental
212 margin zone (CCMZ), excluding coastal upwelling, linked to the rest of the world ocean (« open
213 ocean » zone including upwelling and polar zones). In principle, the CCMZ comprises proximal
214 and distal coastal zones, as defined by Laruelle et al. (2009) (see main text reference list), which
215 includes coastal upwelling in the distal coastal zone. However, in coastal upwelling zones both
216 physical and biogeochemical dynamics are markedly different from those in the CCMZ as
217 represented by Jeandel et al. 2016 (see main text reference list). Indeed, if in the CCMZ the
218 transfer of material from land to ocean plays a major role in physical and biogeochemical
219 processes, in coastal upwelling zones the bSi production is mainly fueled by dSi flux from
220 below (i.e. from deeper in the water column), as it does for the global ocean *sensu lato* (Fig. 1).
221 Therefore, in our synthesis quantifying the Si cycle in the « boundary exchange » zone, coastal
222 upwelling is discarded from the CCMZ and conceptually incorporated to the « open ocean »
223 zone, as shown in Fig. 4. This figure represents a possible Si cycle *assuming steady state* in the
224 CCMZ and in the rest of the world ocean (so called « open ocean »), that is with total inputs =
225 total outputs = 15.6 Tmol-Si yr⁻¹.

226 **5.2 Detailed legend of Fig. 4**

227 Input and dSi fluxes (grey arrows), outputs and biological fluxes (black arrows). In this steady-
228 state scenario total inputs = total outputs = 15.6 Tmol-Si yr⁻¹ (consistent with main text Figure
229 1). Note that (1) in the CCMZ the burial flux of bSi (3.7 Tmol-Si yr⁻¹) and the reverse
230 weathering flux (4.7 Tmol-Si yr⁻¹) (authigenic siliceous material) are fed by the export flux of
231 biogenic silica, and (2) the « open ocean » deficiency in dSi (4.7 Tmol-Si yr⁻¹) is made up by a
232 transfer from the CCMZ. For details about those inputs and outputs refer to the « inputs » and
233 « outputs » sections of the main text. For abbreviations, see detailed legend of Fig. 1 in
234 Supplement (section 1).

235 *Additional comments of Figure 4:*

236 -Estimates of burial rate (planktonic bSi): in the CCMZ (excluding coastal upwelling),
237 according to Rahman et al. 2017 (see main text reference list), $F_{B\ CCMZ} = 3.7\ Tmol-Si\ yr^{-1}$; in
238 the « open ocean » zone, consistent with Fig. 1, $F_{B\ openocean} = 9.2 - 3.7 = 5.5\ Tmol-Si\ yr^{-1}$.

239 -Estimates of reverse weathering flux: in Fig. 4 CCMZ F_{RWCCMZ} equals 4.7 Tmol-Si yr⁻¹,
240 (Rahman et al. 2017, see main text reference list). Reverse weathering in the « open ocean »
241 remains unquantified.

242 -Following Annex 1, bSi production in the CCMZ* is 13% of the total production (255 Tmol-
243 Si yr⁻¹). Consequently, $F_{P(gross)}$ is 33 and 222 Tmol-Si yr⁻¹, for CCMZ and “open ocean”,
244 respectively.

245 -According to Tréguer and De La Rocha (2013) (see main text reference list), the pelagic
246 production to dissolution ratio (D:P) being 0.51 and 0.57, for CCMZ and “open ocean”,
247 respectively. $F_{D(surface)}$ for those compartments is 17 and 124 Tmol-Si yr⁻¹, and F_E is 16 and 98
248 Tmol-Si yr⁻¹, for CCMZ and “open ocean”, respectively.

249 Note than every component of the inputs, outputs, and biological Si fluxes, although interacting
250 between each other, is determined by independent methods, that is there is no overlap in the
251 counting of these fluxes. Therefore, the export production (16.0 Tmol-Si yr⁻¹) in particular feeds
252 both the Si burial rate (3.7 Tmol-Si yr⁻¹) and the reverse weathering flux (4.7 Tmol-Si yr⁻¹).

253 Figure 4 also shows that the “open ocean” bSi production is mostly fueled by dSi inputs from
254 below (92.5 Tmol-Si yr⁻¹), the CCMZ only providing 4.7 Tmol-Si yr⁻¹ to the “open ocean”.

255 *Although specific estuarine sites have been studied (e.g. S19 DeMaster 1983, S20, Raimonet
256 al. 2013), no global estimate is presently available for the estuarine bSi production. Given that
257 most of estuarine waters are turbid we anticipate that the contribution of estuaries to the total
258 bSi of the coastal zone should be small.

*Surface considered: this is the ocean surface minus the Antarctic ocean

*Polar: surface includes the Antarctic Ocean (from the polar front poleward, i.e. 44 10⁶ km²) + arctic zones as defined by Longhurst

*Westerlies: includes the subantarctic zone

*Southern Ocean: includes the Antarctic Ocean and the subantarctic zone (i.e. respectively 44 10⁶ km² + 29 10⁶ km²)
