Modeling the Influence of Diel Variable Processes in the Ocean (Process-Level Description of the Two Scenarios)

Scenario 1. The Ocean as a Net Sink

The dynamic simulation starts from an assumed steady-state situation, in which the only source is a constant background inflow in air. The total sink is about equally divided between net deposition to ocean water and advection out of the system in air. The calculated air/water fugacity ratio was 3.6, indicating near equilibrium condition with a thermodynamic gradient favoring net deposition to water. If all other processes were stopped and only air-water deposition was occurring, the air concentration would reach half its initial value in 14 h. However, the response time of the atmosphere in the model is attenuated by diffusive feedback from the water. The net deposition rate is 25% smaller than gross deposition at steady state, and the air compartment is constantly re-supplied by PCBs from the background source.

Variability in the OC concentration in ocean water had a larger effect on air concentrations than variability in OH radical concentrations, but under this scenario the magnitude of the induced variability was small compared to what was observed in the field. Air concentrations varied only by about 20% in response to variability in ocean parameters (see Figure 3 in the main text). This corresponds to a factor of 1.2, which cannot account for the factor of 2 variability observed in the field measurements. The magnitude of the induced variability is limited by the relatively slow response of the air compartment to changes in the ocean compartment, and by the dynamic coupling and near-equilibrium conditions between air and water, which limit the magnitude of the net flux of PCBs from air to water.

Scenario 2. The Ocean as a Net Source

When the background concentration in air is reduced at the start of the dynamic model run, the model moves towards a new steady state. The lower-air compartment responds quickly to the change in inflow concentration, so if the background air concentration is lowered enough, the fugacity gradient switches and the ocean becomes a net source of PCB to the air (rather than a net sink). The ocean can be a net source to the atmosphere under two different scenarios: (1) If the ocean is “loaded up” with PCBs during the winter, which are then outgassed during the spring/summer (when the cruises took place); or (2) if the area where the diel variability was observed normally had higher PCB concentrations in air, but sampling occurred on days when the air concentration was unusually low (e.g., due to the arrival of relatively uncontaminated oceanic air masses). When the OC content of ocean water is high, the fugacity capacity of the surface ocean is also high, and the fugacity in the ocean water is low. At these times the fugacity gradient is downward, there is net deposition and air concentrations in the lower atmosphere fall. When the OC content of the ocean falls, the fugacity in this compartment rises above that of the lower air compartment and there is net volatilization so that air concentrations rise.
