Abstract

In the upper layers of the Ionian Sea, young Mediterranean Atlantic Waters (MAW) flowing eastward from the Sicily channel meet old MAW. In May 2017, during the PEACETIME cruise, fluorescence and particle content sampled at high resolution revealed unexpected heterogeneity in the central Ionian. Surface salinity measurements, together with altimetry-
15 derived and hull-mounted ADCP currents, describe a zonal pathway of AW entering the Ionian Sea, consistent with the so-called cyclonic mode in the North Ionian Gyre. The ION-Tr transect, located ~19-20°E- ~36°N turned out to be at the crossroad of three water masses, mostly coming from the west, north and from an isolated anticyclonic eddy northeast of ION-Tr. Using Lagrangian numerical simulations, we suggest that the contrast in particle loads along ION-Tr originates from particles transported from these three different water masses. Waters from the west, identified as young AW carried by
20 a strong southwestward jet, were intermediate in particle load, probably originating from the Sicily channel. Water mass originating from the north was carrying abundant particles, probably originating from northern Ionian, or further from the south Adriatic. Waters from the eddy, depleted in particles and Chl-a may originate from south of Peloponnese, where the Pelops eddy forms.

25 The central Ionian Sea hence appears as a mosaic area, where waters of contrasted biological history meet. This contrast is particularly clear in spring, when blooming and non-blooming areas co-occur. Particle abundance *in situ* measurements are useful to discriminate water masses and derive circulation, together with T-S properties.

Interpreting the complex dynamics of physical-biogeochemical coupling from discrete measurements made at isolated stations at sea is a big challenge. The combination of multiparametric *in situ* measurements at high resolution with remote
30 sensing and Lagrangian modeling appears as one proper way to address this challenge.

1 Introduction

The Ionian Sea is a cross road where young modified Atlantic water (AW) flowing from the Sicily channel meets older MAW flowing from the East, and water coming from the Adriatic Sea (Malanotte-Rizzoli et al 1997). Circulation in the North Ionian, and thus the path of AW spreading, is variable and two alternate states have been proposed, the anticyclonic and cyclonic mode of the so called North Ionian Gyre (NIG, Gačić et al 2010). The direction of the NIG has a strong influence on the dispersal of water masses and properties in the Ionian basin, also impacting its productivity (Lavigne et al 2018)..

Although the circulation in the Ionian basin has been documented according to seasons and NIG modes (Malanotte-Rizzoli et al 1997, Gačić et al 2011, Menna et al 2019), the fine scale pathways of AW crossing Ionian Sea have only been seldom sampled. The contact zone between water masses can only be characterized through high resolution sampling, potentially revealing small scale horizontal discontinuities in properties missed by traditional coarse sampling.

Ionian Sea is generally considered oligotrophic (Boldrin et al 2002), with a north-south gradient of Chl-a (d'Ortenzio et Ribera d'Alcala 2009). However, it is not homogeneous, as distinct phytoplankton communities associated to the main water masses have been described (Casotti et al 2003). Three main phytoplankton communities were associated with water coming from Adriatic in the north west, water from the Eastern Mediterranean in the north east and AW from Sicily channel to the south. Zooplankton community was also contrasted between northwestern and eastern Ionian (Mazzocchi et al 2003).

The influence of water masses on particle distribution is less described. Presently few data are available on the horizontal distribution of particles in the Ionian Sea. These data are mostly from transmissometry, bottle derived particulate matter filtration (Rabitti et al 1994, Boldrin et al 2002, Karageorgis et al 2008, 2012) and few data are from optical devices (Ramondenc et al 2016).

The objective of this paper is to document an abrupt change in particle abundance along a high-resolution multi-parametric transect located at the boundary between water masses in the central Ionian Sea, to propose scenarios of histories of these waters masses and discuss implications.

2 Material and Methods

The PEACETIME cruise (<http://peacetime-project.org/>, Guieu et al 2020) was conducted during late spring conditions from May 10th to June 11th, 2017 on board the R/V *Pourquoi Pas ?*. Along the 4300 km transect covering western and eastern Mediterranean basin, 10 short stations (with an average duration of 8 hours) and 3 long stations (duration of 4-5 days) were performed. The ship entered Ionian Sea on May 22nd and the last station (ST8) in the region was occupied on May 30th as detailed in table 1.

60 At stations, Rosette casts were carried out (0-500 and 0-bottom). The "classical" Rosette was composed of a CTD (pressure, temperature and salinity of seawater, dissolved oxygen concentration, photosynthetically active radiation (PAR), beam transmission (at 650 nm), chlorophyll a fluorescence. This instrumental package was also composed of a sampling system : 24 12-L Niskin bottles could be fired at specified levels during upcasts. Water from the classical Rosette was used to quantify oxygen, nutrients, Dissolved Organic Carbon, Particulate Organic Carbon and Nitrogen and pigments using HPLC
65 (see Guieu et al 2020, and Marañón et al 2020 for detail on HPLC).

2.1 High resolution vertical sampling

Between stations, transects with a Moving Vessel Profiler (MVP) were carried out. In the Ionian Sea two transects were achieved, ION-Tr and a very short ST8-Tr (figure 1). MVP200 ODIM Brooke Ocean performed vertical profiles, at a spatial resolution of ~1 nm, with the nearly vertical free falls of the Multi Sensor Free Fall Fish type I equipped with a AML
70 microCTD, a WetLab ECO fluorimeter, and a ODIM Brooke Ocean Laser Optical Plankton Counter (LOPC). The T and S of the microCTD were calibrated with the rosette CTD. The LOPC recorded particle size and abundance distributions: the instrument records the cross-sectional area of each particle passing through its laser beam (Herman et al., 2004; Herman & Harvey, 2006) for a size range between 100 μ m and a few centimeters. If a particle is recorded by at least 3 diode elements, it will be recorded as a multi-element plankton (MEP), in contrast to single element plankton (SEP). LOPC also provides
75 information about the MEPs allowing to compute an attenuation index (AI). The living fraction of particles can be estimated, using a calibration based on comparison with plankton net tows (Espinasse et al., 2018). The sampling volume was estimated using the LOPC sampling tunnel surface multiplied by the depth increment estimated with the pressure sensor. Given the fish free-fall velocity of ~4 m/s and the LOPC acquisition frequency (2 Hz), we binned the LOPC over 5-m vertical bins. As the surface docking depth of the MVP fish was not constant, the first bin (0–7.5 m) was discarded from the analysis. The
80 LOPC abundances were redistributed into log-scale size bins for easier analysis. Total abundance (e.g., abundance over the full LOPC size range) and parameters of the size distribution were computed (slope and intercept of the Normalized Biomass Size Spectra (NBSS), e.g. Espinasse et al., (2018). We thus have access to vertical profiles of total abundance of particles (particles per cubic meter) at almost each kilometer during the MVP transects.

2.2 Underway measurements

85 The TSG, equipped with a SeaBird SBE21, was connected to a continuous surface water flow-through system that pumped seawater at 2-m depth. Output data were sea surface temperature and Salinity every minute all along the cruise route. Horizontal velocity was measured with a hull mounted ADCP.: RDI Ocean Surveyor 150kHz. Data treatment used CASCADE software version 7.1 (Le Bot et al 2011) and LATEXtools toolbox (Petrenko et al., 2017, Doglioli et al., 2013, <https://people.mio.osupytheas.fr/~doglioli/latextools.htm>).

90 2.3 Automated cytometry

Surface phytoplankton community was analysed using an automated flow cytometer (Cytosense benchtop flow cytometer from CytoBuoy b.v) installed on a dedicated continuous sampling system set up to pump surface water (at 5m depth). The Cytosense automated flow cytometer was equipped with a 120 mW, 488 nm laser beam. The volume analyzed was controlled by a calibrated peristaltic pump and each particle passed in front of the laser beam at a speed of $2 \text{ m}\cdot\text{s}^{-1}$. The particle resolved size range varied from $<1 \text{ }\mu\text{m}$ up to $800 \text{ }\mu\text{m}$ in width and several hundreds of μm in length for chain forming cells. The trigger to record a signal was based on pigment fluorescence. Stability of the optical unit was controlled before and after the cruise using fluorescing $2 \text{ }\mu\text{m}$ Polyscience beads, and a set of silica beads of 1.0 , 2.0 , 3.0 , 5.0 , $7.0 \text{ }\mu\text{m}$. The size estimates of cells were retrieved from the silica beads FWS signature, and enabled to separate pico-nano-microphytoplankton size classes. The instrument allowed for the quantification of pico-, and nanophytoplankton populations, up to microphytoplankton when abundant enough in the 5 mL analyzed. Seven groups were resolved. One group of picoeukaryotes (mean size $2.81\pm 0.19 \text{ }\mu\text{m}$), three groups of nanoeukaryotes (Nanoeukaryotes1, 2 and 3, mean sizes of 4.76 ± 0.13 , 7.16 ± 0.35 and $10.64 \pm 2.18 \text{ }\mu\text{m}$ respectively), Synechococcus like ($1.04\pm 0.12 \text{ }\mu\text{m}$), Chryptophytes like ($6.00 \pm 0.93 \text{ }\mu\text{m}$) and a coccolithophore like group ($5.37\pm 0.14 \text{ }\mu\text{m}$). Each phytoplankton group was manually clustered thanks to the Cytoclus® (<http://www.cytobuoy.com/products/software/>) dedicated software.

105 2.4 Satellite data

Several remote sensing datasets were exploited using the SPASSO (Software Package for an Adaptive Satellite-based Sampling for Ocean campaigns, <https://spasso.mio.osupytheas.fr/>; last access: 2 Oct. 2020). Altimetry data was obtained from the AVISO Mediterranean regional product. Delayed-time L4 maps of SST Sat (Mediterranean Sea – High Resolution L4 SST Reprocessed; Nardelli et al., 2013; Pisano et al., 2016) and Chl Sat a (Mediterranean Sea Reprocessed Surface Chlorophyll Concentration from Multi Satellite observations) were retrieved for the period of the cruise, on regular grids of $0.04 \times 0.04 \text{ }^\circ$ resolution for SST Sat and of $1 \times 1 \text{ km}$ resolution for Chl Sat a from CMEMS - Copernicus Marine Environment Monitoring Service (<http://marine.copernicus.eu/>). SPASSO provided several Lagrangian diagnostics of the altimetry-derived current field, such as the Finite scale Lyapunov Exponent (FSLE) computed using the algorithm of d'Ovidio et al. (2004), in order to help in positioning the sampling transect and stations taking into account the ocean dynamics. This approach was successfully adopted during previous cruises such as LATEX (Petrenko et al, 2017), KEOPS2 (d'Ovidio et al., 2015), OUTPACE (Moutin et al, 2017).

2.5 Lagrangian numerical simulations

In order to estimate the origins of the sampled surface water along transect ION-Tr, the ARIANE package (Blanke and Raynaud, 1997) was used to predict surface trajectories of water particles, using surface geostrophic velocities derived from altimetry and wind from WRF model. The daily gridded surface geostrophic velocity fields from Copernicus Monitoring

Environment Marine Service (CMEMS) were used, with a resolution of $1/8^\circ$, using the near real time data, validated by an accurate comparison with both the hull-mounted ADCP-data and the SVP drifters deployed during the cruise (Barrillon et al 2019). The numerical particle positions were initialized in a polygon around the ship's track on May 29 (longitude:18-20.1, latitude: 35.4-35.9, $\pm 0.2^\circ$ in latitude). This polygon takes into account possible offset between in situ velocity and satellite
125 derived geostrophic velocity. Given the daily time series of the surface velocity field, the ARIANE package computes numerical particle trajectories through a backward or forward integration time. The so-called "qualitative" mode is chosen: each particle trajectory can be followed step by step through the integration time. Only surface trajectories were considered. 10000 particles chosen randomly inside the launch area were advected backward for one month. This duration was chosen as a trade-off between source identification and error accumulation along the trajectories. The particle trajectories and final
130 positions were analyzed to determine the main source areas.

The cruise data are available on LEFE-CYBER database.

3 Results

3.1 Oceanographic context

135 Time series of satellite Chl-a showed that surface phytoplankton concentration was decaying since mid-March (figure 2). Since the end of April, the Ionian Sea was steadily warming while Chl-a concentration remained low ($0,09 \text{ mg.m}^{-3}$) indicating the absence of significant surface production events. On average over April-May, maximum Chl-a concentrations were observed in the area South of the Strait of Messina and in the Gulf of Taranto (not shown).

140 At the end of May in the Ionian basin, satellite imagery (figures 3A and 3B) shows a slight large scale meridional gradient of SST and Chl-a, with warmer and low-Chl water to the south and colder and medium Chl-water to the north. In addition, a strong variability was observed at the mesoscale with cold and Chl-rich filaments south of the Strait of Messina and south of Sicily, extending toward the center of the basin. Several cyclonic and anti-cyclonic structures were visible in the center of the basin.

145 The along route salinity showed a general increase toward the east and the north. On the northern part of the route (SAV-ST7-ION), there was a transition from medium salinity to the north to low then high salinity at the easternmost end of the route close to long duration station ION. On the southern part of the route (ION to ST8), there was an alternation of low and high salinity water, sampled during ION-Tr transect. Then west of 18°E , salinity was stable lower than 38.2 up to the Sicily
150 channel. Therefore SAV and ST7 were in medium salinity waters, ION (ST8) was in high (low) salinity waters, while ION-Tr crossed waters with contrasted salinities.

155 The two cytometric groups showing contrasted distribution and sufficient abundance are shown (figures 3C and 3D). In the Ionian Sea, nanoeukaryotes¹ and coccolithophore like showed a distribution consistent with salinity, with higher values in saltier water except southeast of Sicily. The pattern was also mostly consistent with satellite Chl-a, with high abundances southeast of Sicily and south of the Strait of Messina. However, along ION-Tr, abundance was variable while satellite Chl-a was fairly constant.

160 Altimetry-derived surface geostrophic current showed a general circulation with an anticyclonic flow across the basin (figure 4A). South of Sicily, water entered the Ionian Sea around 36°N along a southeastward path, progressed eastward along 35.5°N, then veered southwestward close to 19.5°E. East of 18°E, the currents show a pattern consistent with the intense (~0,5 m/s) currents measured by the hull-mounted ADCP along the ship route, depicting an anti-cyclonic meander, more intense on its eastern flank. There is a small spatial offset between altimetry and ADCP (~0.4°, figure 4B). The southwestward branch of this meander was located approximately in the center of the ION-Tr transect, while the ION station
165 was located on the eastern border of the meander. Altimetry-derived FSLE field (figure 3), as well as the time series of ADT (annex A) showed that this anticyclonic meander east of 18°E was stable during May. The southwestward jet sampled during ION-Tr coincided with a slightly cooler and higher Chl-a filament than surrounding waters, as shown on figures 3A and 3B.

3.2 Distribution of properties along transect ION-Tr

170 Based on the salinity distribution (figure 5), ION-Tr can be divided into three parts. From West to East, a western part (noted W) with salinity >39, except the fresher top layer 0-30m, a center part (noted C) with a low salinity vein (<38.7) extending to 70m deep, and an eastern part (noted E) with quasi-homogeneous salinity on the vertical, slightly lower than in W (39). Hereafter we define three pseudo-stations along ION-Tr, named ION-W, ION-C, ION-E. Note that ION long duration station was located very close to the eastern part of ION-Tr (figure 1), thus ION-E and ION can be approximated as a single station.

175 This salinity distribution coincided with pattern of ADCP currents magnitude, with ION-W and ION-E being in quiescent water (current < 0.2 m/s), while ION-C correspond to a strong (>0.3 m/s) southwestward jet extending from the surface to 300m depth. The total abundance of particles, as well as Chl-a fluorescence clearly contrasted between ION-W and ION-E. In ION-W, particle abundance was low (<5 10⁴ #.m⁻³), essentially concentrated within the 20-30m layer. Fluorescence was rather homogeneous with a broad maxima around 110m. In ION-E part, abundance was much higher (>2 10⁴ #.m⁻³) with a deep maximum at 100m depth (values around 1 10⁵ #.m⁻³) close to the depth of the Deep Chlorophyll Maximum (DCM) and
180 also high particle abundance in the upper 20-90m layer (~ 3 10⁴ #.m⁻³). ION-C was distinct from ION-E and ION-W in term of vertical distribution and abundance of particle as well as fluorescence, with the low salinity vein coinciding with higher particle abundance and the maximum fluorescence being located ca 70m, at the interface between low salinity waters and underlying waters.

185 The T-S distribution of ION-Tr (figure 6) mirrored the distributions of stations ST8 and ION. Water at ION-C is similar to ST8 for densities greater than 1028 (ie deeper than 25m). ION-E is similar to ION with more scatter. ION-W does not match the other stations. Northern stations ST7 and SAV had similar water masses properties, distinct from ST8, ION and the ION-Tr profiles.

190 At the surface, cytometric groups also showed contrasting abundances along ION-Tr (figures 3C and 3D). Horizontal sampling resolution did not allow to distinguish ION-C region. From west to east with respect to ION-C, nanoeukaryotes1 increased from low values (as mean \pm SD, 487 ± 52 cells.cm⁻³, n=27, 18-19.5°E) to higher values (659 ± 50 cells.cm⁻³, n=117, >19°5E). Coccolithophore like group also increased (176 ± 18 cells.cm⁻³ against 192.47 ± 13 cells.cm⁻³). Conversely, picoeukaryotes abundances decreased eastward (653 ± 94 cells.cm⁻³ vs 462.8 ± 76 cells.cm³, not shown). The other groups did not evidence high changes in abundances.

195 3.3 Comparison of vertical distribution across stations

Carousel measurement performed at the SAV, ST7, ST8 stations together with the one from the ION transect are shown in figure 7. These vertical profiles allow a finer analysis of the contrast between stations and among parts of ION-Tr. Consistent with figure 6, Salinity increased from ST8 to ION-E. If we take apart the upper 0-25m depth corresponding to the mixed layer (ML), couples of stations were similar: ION-C and ST8, ION-E and ION-W, ST7 and SAV. A narrow (<10m
200 thick), lower salinity layer was present at 30m on every profile except ION-E. The surface pycnocline was located at 10 to 25m, followed by a steep thermocline down to 60-80m. Surface nitrate was depleted everywhere. Nitracline depths increased from 60m at SAV up to 90m at ION, together with nitrate concentrations below the euphotic zone.

DCM was always present, but its intensity was highest at ST8 and lowest at ION-W and ION-C, where fluorescence was more diluted. The depth of DCM corresponded to the top of nitracline and to the bottom of the euphotic zone (~90m at ION).
205 Profiles of particle abundance were strongly variable among stations. The depth-integrated abundance was highest at SAV and lowest at ION-W. Some profiles had several maxima. At ST8 and ION-E, the main peak was just above the DCM depth, and a secondary peak was present above DCM at ~20m, also present at ION-W. SAV profile was different with a large peak at 50m, above DCM, and a surface peak at 10m.

210 Considering particle parameters (table 2), the slopes of the NBSS were similar for stations ST8, ION-W, ION-C (0,92), and slightly lower for SAV and ION-E (0,85), indicating more abundant larger particles. On a depth average, referring to the calibration given in Espinasse et al (2018), MEP proportion indicated that at ION-C and ION-W, particles counted were ~60% zooplankton, while at ION-E, ST8 and SAV particles were mainly detritus (~75-90%) ie non-living particles such as aggregates produced after intense primary production. AI was similar across depth layers but higher at ION-E (0.1 against
215 0.05 and 0.08), while MEP was more abundant in the 50-150m layer, where the particle maxima were observed.

3.4 Origin of particles

Lagrangian simulations showed that the water parcels observed along ION-Tr originate from four main regions (figure 8). One located south, one located west and two located north of ION-Tr. As the altimetry-derived velocity was shifted $\sim 0.4^\circ$ west with respect to in-situ velocity from ADCP (figure 4B), the initial positions of numerical particles were extended westward to 18°E . Considering the main pathways of particles, four source regions can be defined (South origin So, West origin Wo, North origin No, Eddy origin Eo). Along ION-Tr, the proportion of each origin region showed a rather clear pattern, with some overlap in the center (figure 8F). Referring to the three parts identified along ION-Tr, ION-W was in waters mainly originating from Eo. ION-C was mainly originating from Wo but also from Eo and to a lesser extent from So. ION-E was only originating from No. Finally, west of 18.6°E , beyond the limit of the actual transect, So was the main contributor.

4 Discussion

4.1 Surface circulation and distribution of water masses in the Ionian Sea

Surface circulation, together with the along track surface salinity distribution, describe one pathway of MAW penetrating into Ionian Sea (figures 3 and 4). Here, this pathway is approximately zonal along latitude 36°N from the Sicily Strait up to 19°E , then veering southwestward. This pathway is supported by the similarity of water masses properties sampled at ST8 and ION-C (figures 6 and 7) and illustrated by backtracked trajectories (figure 8, Western origin), indicating a *ca* one month travel between 15°E and 19.5°E . It is also supported by the absence of transport barriers east of ST8 shown by FSLE (figure 3). North of 36°N , the similarity of ST7 and SAV water masses properties (figure 6) also supports a single origin of water masses in the Northern Ionian.

This distribution of MAW in the Ionian Sea is consistent with a cyclonic mode of the so called North Ionian Gyre (NIG, Gačić et al 2010), that characterizes the circulation in the Ionian Sea north of *ca* 35.5°N . In the cyclonic mode of the NIG, MAW follows a rather direct East-SouthEast path, while saline water from the Levantine basin enters the Northern Ionian Sea from the East, and current flows southwestward along Calabria (Menna et al 2019). As observed by altimetry, the NIG was cyclonic since 2011 (Menna et al 2019), and reversed to anticyclonic in the second half of 2017 (von Schuckmann et al., 2019), after our sampling.

It is interesting to note that the southwestward jet sampled along ION-Tr is a persistent feature of Ionian Sea circulation, generally located at *ca* 20°E , 36°N and directed southward (see figure 2 in Menna et al 2019, Celentano et al 2020, Berline et al 2014). It is present during cyclonic and anticyclonic modes of the NIG. It pertains to the northern branch of the Mid Ionian Jet (MIJ).

250 Cyclonic circulation of the NIG implies a downwelling of nutricline at the northern border of the NIG, and an upwelling of
nutricline in the central NIG (Civitaresse et al 2010, Lavigne et al, 2018). Our observations of nutricline depth (isoline $1\mu\text{M}$ at
(2018). Cyclonic mode also favors higher Chl-a in the center NIG, and a late winter bloom (Lavigne et al, 2018). However
the Chl-a evolution over 2017 only shows a weak bloom in the Northern Ionian (figure 2). This may result from a weak
winter buoyancy loss, independent of the NIG circulation, as pointed out by Lavigne et al (2018). The last increase of Chl-a
255 occurred in the last week of April 2017, then Chl-a decreased and reached its minimum value around the end of May, during
our sampling.

4.2 Origin of water masses sampled along ION-Tr

In the center of ION-Tr, a strong current is associated to a low salinity vein (down to 38.4, figure 6). The center current
dynamically separates the two parts of the transect, and this separation is stable as supported by the FSLE ridge (figure 3).
While the density stratification is similar along the transect, particle and Chla distributions show a striking difference from E
260 to W. At ION-E, there is 60% higher particle abundance, and twice higher biovolume compared to ION-W (table 2),
essentially due to particles with and equivalent spherical diameter (ESD) smaller than $500\mu\text{m}$. At ION-E particles are filling
the pycnocline from 1028 to $1028.7\text{ kg}\cdot\text{m}^{-3}$, with a maximum associated to a narrow DCM at 100m, while at ION-W
particles are only present in the density layer 1028-1028.2, and the DCM is broad and weak, not associated to a particle
peak.

265 The distinct Chl-a and particle distributions along ION-Tr suggest that waters sampled at ION-E and ION-W have distinct
histories of biological production. One hypothesis is that these water masses originate from distinct locations. To explore this
hypothesis, backtracking of particle trajectories was carried out and led to three main origins of water sampled along ION-Tr
(Wo, No and Eo, as So is only marginally contributing to the transect), that correspond to different part of the transect (figure
8). When two origins overlap, we only consider the dominant origin. Water found at ION-C would be transported from the
270 West (Wo), ie the Sicily channel, while water found at ION-E (ION-W) would be transported mostly from the Northern
Ionian (No), and from an eddy located North (Eo) respectively. Referring back to the general circulation in the Ionian, the
ION-Tr appears to be at the crossroad between waters from the North Ionian, waters from the MIJ coming from the West and
waters trapped into an anticyclonic eddy.

4.3 Biological history of water masses sampled along ION-Tr

275 LOPC detects particles of $\text{ESD} > 100\mu\text{m}$ (median ESD was $130\text{-}145\mu\text{m}$ along ION-Tr), typically aggregates formed as a
result of intense primary production (Briggs et al., 2020; Martin et al., 2011). Once produced, aggregates can fragment or
coagulate, be grazed, be degraded by bacteria attached to them and sink out of the surface layer (Le Moigne 2019,

Stemmann et al 2004). Therefore the particle abundance in the euphotic layer generally peaks shortly after a primary production event, then decreases with a speed depending on several factors.

280

Although the age of particles cannot be determined from their size distribution, we can make some hypothesis. At the time of sampling, the whole Ionian Sea was stratified, mixed layer was shallow (~25m) and nitrate was fully depleted over the euphotic zone except at SAV, indicating stable, post-bloom conditions. As surface Chl-a continuously decreased since the end of April (figure 2), this suggests that the last surface primary production event around ION station occurred about a month before our sampling. This is longer than the time lag observed between primary production and subsequent export in large mesocosms experiments (Stange et al., 2017). Therefore, freshly formed particles are not likely.

285

The sinking speed of particles depends on their mineral composition (Le Moigne 2013), shape (Laurenceau et al., 2019) and on the phytoplankton community (Riley et al 2012, Guidi et al 2009). Consistent with our cytometric results, the pigment composition available at ST7, ST8 and ION show a community dominated by nanophytoplankton (>60% of total Chl-a) in the upper 80m, while diatoms were abundant at DCM depth (41-51% of total Chl-a, see Marañón et al 2020). The dominance of nanophytoplankton and coccolithophores were also found by Boldrin et al (2002) in the Northern Ionian Sea (38,5°N). Thus, in the upper 80m small cells (typically <5µm in diameter) do not favor the production of large aggregates and direct export (Richardson and Jackson 2007), conversely to DCM.

290

295

Second, aggregates are slowed down by density gradients, because of the equilibration time of their interstitial water (MacIntyre et al 1995, Prairie et al 2015). Therefore pronounced stratification can locally increase their abundance, as reported in numerous settings (Espinasse et al 2014, Marcolin et al 2013, Ohman et al 2012). This explains that all profiles have a particle peak at the main density gradient, just below the mixed layer depth (figure 7). However, this mechanism does not explain deeper peaks observed at 60m and 90m.

300

Finally, zooplankton can also contribute to the particle production through fecal pellet, and transformation (sloppy feeding), but we are lacking zooplankton abundance data for ION-C and ION-W.

We now review the potential processes that led to the observed particles and Chl-a distributions along ION-Tr, from west to east.

305

4.3.1 Western part

At ION-W, below the weak particle peak (figure 7, $2 \cdot 10^4 \# \cdot m^{-3}$) associated with the density gradient at the bottom of the mixed layer, abundances steeply decrease and reach minimum values at 80m ($1 \cdot 10^4 \# \cdot m^{-3}$). Such a low particle abundance in

310 the top 100m was not observed anywhere else across all PEACETIME LOPC profiles (~800 casts, Guieu et al, 2020). The
Chl-a concentration is also lower and very patchy compared to ION-E. As nitracline depth was shown to be highly correlated
with the depth of the 1028,9 isopycnal in the Ionian (Lavigne et al 2018), the steep deepening of this isopycnal from ION-E
to ION-W suggests a much deeper nutricline at ION-W than at ION-E (figure 5). Together, these observations emphasize the
very oligotrophic character of station ION-W. Considering the backward trajectories (figure 8), this low abundance may
315 result from two origins (i) waters trapped into an anticyclonic eddy (Eo), or (ii) waters from the southern Ionian (So), which
is more oligotrophic and where phytoplankton concentration peak earlier in the year (D'Ortenzio and Ribera d'Alcala 2009).
For hypothesis (i), analysis of the evolution of altimetry (annex A) revealed that the eddy stayed coherent during the first six
months of 2017 while slowly moving from the eastern Ionian. This eddy may have trapped waters from the eastern Ionian,
more oligotrophic (Casotti et al 2003), and the vertical velocities in the center of the anticyclonic eddy may have accelerated
320 the export of particles, as observed in the eastern Mediterranean (Waite et al 2016). For (ii), particles profiles in the southern
Ionian obtained with UVP in July 2008 (Picheral et al 2010) (ecotaxa.obs-vlfr.fr, Kiko et al 2020) did not show such low
abundances, therefore not supporting this hypothesis.

4.3.2 Center part

At ION-C, the backtracked trajectories indicate two overlapping origins (Eo and Wo mainly). However the low salinity vein
325 extending down to 70m is a clear footprint of AW observed at ST8. Given the distribution of surface salinity from TSG
(figure 3A and 3B) this gives more support to Wo. As with ION-E, significant particles abundance above DCM suggest that
particles were produced upstream, near ST8 or further west, possibly in the enriched area south of Sicily, then advected to
central Ionian.

4.3.3 Eastern part (ION station)

330 At ION-E DCM, microphytoplankton was dominant (Marañón et al 2020). The DCM was associated to the bottom of the
euphotic zone (~90m at ION), but not to a density gradient. Therefore the particle peak associated with DCM probably result
from aggregates produced locally, from diatoms decay and fecal pellet production by zooplankton. Association of DCM with
a particle peak was not observed in similar settings (see station A in Espinasse et al 2018), which suggests that the plankton
community at ION-E DCM enhances aggregate production, perhaps through mucous production, as mucous was reported in
335 sediment traps in the Northern Ionian (Boldrin et al 2002).

Above DCM, significant particle abundance ($2-3 \cdot 10^4 \text{ \#} \cdot \text{m}^{-3}$) was observed together with phytoplankton dominated by
nanophytoplankton (Marañón et al 2020). This significant particle abundance above DCM is also observed at SAV and ST8,
with much higher peak concentration at SAV than at ST8 ($1.5 \cdot 10^5 \text{ \#} \cdot \text{m}^{-3}$ and $3-4 \cdot 10^4 \text{ \#} \cdot \text{m}^{-3}$ resp). When particles are
340 suspended or sink slowly with respect to the horizontal velocity, particle abundance act as tracer for horizontal advection

(e.g. Karageorgis et al 2012, Chronis et al 2000). We argue that at stations SAV, ST8 as well as at ION-E, the abundance of particles above DCM is a remainder of past surface production event that has not been exported out of the surface layer yet. In the Northern Ionian, a POM maximum above DCM (0-50m) was also reported by Rabitti et al (1994), and attributed to relict bloom. As above DCM waters are depleted in nutrients, above-DCM particles at ION-E could be transported from an
345 area where phytoplankton production was more intense and shallower, such as SAV according to the backward trajectories and the vertical profiles. This continuity is supported by the similar slope of the particle size spectra at SAV and ION-E (table 2). It is also supported by the higher surface abundance of cytometric counts of nanoeukaryotes and coccolithophores at SAV, along Calabria and at ION-E with respect to the other parts of the route (figures 3C, 3D). During transport from SAV to ION-E, particle abundance above DCM may have decreased because of the processes mentioned earlier.

350 In the upper 0-90m layer, nutrients were depleted and nanophytoplankton was dominant. Nanoeukaryotes abundances were stable during the five days of occupation of ION station, according to cytometric counts (not shown). This implies an active nutrient recycling, probably linked to the particle associated microbial community, also supported by the high bacterial production in the layer 0-100m reported by Marañón et al (2020) at ION.

355 ION-E particle characteristics are closest to the ‘continental shelf’ habitat type as defined by Espinasse et al (2014), in the Gulf of Lion in early May. The integrated particle abundance is about half ($18,7 \cdot 10^3 \text{ \#/m}^2$ vs $38 \cdot 10^3 \text{ \#/m}^2$), the average AI is lower (0,08 vs 0,2), the %MEP is higher (6 vs 1,8), and the NBSS slope is similar but steeper (0,85 vs 0,79). Zooplankton abundance was slightly higher ($300 \cdot 10^3 \text{ ind/m}^2$ vs $206 \cdot 10^3 \text{ ind/m}^2$, see Feliu et al 2020, but this value may be biased high due to the combination of two mesh sizes (100 and 200 μm) instead of one (120 μm in Espinasse et al 2018). Thus ION-E was
360 characterized by porous aggregates, with a rather high contribution of large aggregates (%MEP).

Taking into account Chl-a, nanophytoplankton abundances, significant particle load above DCM and high bacterial production, ION station was not strongly oligotrophic, possibly under the influence of particles transported from North Ionian.

4 Conclusions

365 High resolution sampling of water masses, including fluorescence and particle contents revealed unexpected heterogeneity in the central Ionian Sea. Surface salinity measurements, together with altimetry and ADCP currents, describe a zonal pathway of AW entering into Ionian Sea, consistent with the cyclonic mode of the North Ionian Gyre. The ION-Tr appears precisely located at the crossroad of three water masses, coming from the West, North and from an isolated anticyclonic eddy. Water mass originating from the north carried abundant particles, probably originating from North Ionian, or further from the
370 Adriatic. Waters from the eddy were depleted in particles, and probably nutrients, and may originate from the Pelops eddy

area, south of Peloponnese. Waters from the West, carried by a strong jet, were intermediate in particle load, probably originating from the Sicily channel, carried by AW.

Even away from the coasts, the central Ionian Sea appears as a mosaic area, where waters of contrasted biological history meet. ION station is potentially influenced by particles transported from the North Ionian Sea. This contrast is probably amplified in spring, when blooming and non-blooming areas co-occur. Long distance particle transport appears as a significant contribution to particulate matter load, together with atmospheric input.

The small scale heterogeneity of particle abundance revealed here emphasizes the spatial decoupling between particle production and particle distribution. Such decoupling added to the time lag between production and export of particles (Stange et al 2017) may have large impact on assessing the efficiency of carbon export from the surface ocean (Henson et al 2011). This also implies that neutrally buoyant particles can sustain production away, further horizontally and to deeper depths. Interpreting the complex dynamics of physical-biogeochemical coupling from discrete measurements made at isolated stations at sea is a big challenge. The combination of multiparametric in-situ measurements at high resolution with remote sensing and Lagrangian modeling appears as one proper way to address this challenge.

540 **Table 2. LOPC particle derived parameters for ION-Tr, ST8 and SAV, for three depth layers. Abund : Total abundance and BioV : total biovolume.**

545

Figure 1. Bathymetry of the Ionian Sea (isobaths 100, 1000, 2000, 3000, 4000m) with the locations of stations (black squares), transect and transect parts (blue line and dots). Schematic circulation (dark blue arrows) for cyclonic conditions redrawn from Menna et al (2019).

550 **Figure 2 : Time series of A) 8-day satellite Chl-a and B) daily SST prior to sampling, averaged over the northern Ionian Sea (16° to 22°E, 33° to 40°N). Sampling at ION-Tr is marked by the dashed vertical line.**

555

Figure 3. A) Satellite SST (May 29-30th, night, °C). B) Chl-a (May 30th, mg/m³). On panels A and B, underway surface salinity from TSG is overlaid as dots, darker for saltier water. C) Underway surface abundance (cells/cm³) of nanoeukaryotes1 group from cytometry. D) Underway surface abundance (cells/cm³) of coccolithophore like group from cytometry. On all panels, FSLE ridges are overlaid in light grey (>0,15 day⁻¹). Stations positions are marked as red squares and ION-Tr parts as blue dots as figure 1.

560

Figure 4. A) Absolute Dynamic Topography (ADT, color) and surface geostrophic circulation from altimetry averaged over period May 22-30th (black arrows). Underway ADCP currents are overlaid (red arrows). ION-Tr parts marked as blue dots as figure 1. B) Velocity along ION-Tr transect derived from altimetry for May 29th and measured with ADCP .

Figure 5. Variables sampled along ION-Tr transect from MVP, plotted as depth vs longitude. a) Salinity, b) ADCP current magnitude, c) Fluorescence and d) Total particle abundance. Density and current magnitude are overlaid as black contours on all panels. The three parts of the transect where ION-W, ION-C, ION-E pseudo-stations are located are delimited by black vertical lines. ION station position is marked as red dot on top of each panel.

570

Figure 6. TS-diagram for stations ION, SAV, ST7, ST8 (top) and for ION-Tr parts (bottom), ION-W, ION-C, ION-E.

575 **Figure 7. Vertical profiles of variables at ION, SAV, ST7, ST8 (top) and for ION-Tr parts (bottom), ION-W, ION-C, ION-E. Panels A and F Salinity, B and G density, C Nitrate, D and H Chl-a, E and I total particle abundance. Note that particles were not quantified at ST7.**

580 **Figure 8. Backward Lagrangian trajectories for particles launched along ION transect and tracked for one month, with average**
ADT and surface currents averaged for period May 1-30th. Trajectories are separated according to the four major origins. panel A
for Wo, B for No, C for So, D for Eo. Black dots are the final positions. E) Final positions of particles for each origin. F)
Proportion of each origin along ION-Tr computed for each 0.1° of longitude. The three parts of ION-Tr shown on figure 5 are
plotted at the bottom.

585 **Supplementary material**

Appendix A. Absolute Dynamic Topography evolution for period Jan 1st-June 15th 2017. Ship track is marked as thin black line
and ION-Tr as thick black line. The anticyclonic eddy sampled during ION-Tr is visible during the whole period.
