Abstract

The health problems caused waterborne pathogens bacteria belonging to the Enterobacteriaceae family are aggravated by the rise of antimicrobial resistant bacteria phenomenon. This has been identified as one of the biggest global health challenges. The present study aims to make a comparative approach of the sensitivity/resistance to antibiotics of 4 Enterobacteriaceae *Enterobacter cloacae*, *Citrobacter freundii*, *Salmonella typhi* and *Shigella sonnei* isolated from wastewater, streams and groundwater in Yaounde town (Cameroon, Central Africa). Bacteria were isolated using standard methods their identification using the API 20E systems. The antibiogram tests were carried out using the Müller-Hinton antibiotic disc diffusion method. Results showed that inhibition diameters of antibiotic varied ($P < 0.05$) with respect to the bacterial species on one hand, and with respect to the type of water harbored cells on the other hand. The proportion of bacterial strains of each isolated species, and which were sensitive or resistant varied from one antibiotic to another within the same antibiotics family. For β -lactams tested, no *E. cloacae* strain has been sensitive. The proportion of sensitive strains of other species varied between 5.88% and 23.53%. For the 2 aminoglycosides tested, 5.88% of the strains of each isolated species were resistant to gentamycin. Of the 3 quinolones tested, all strains of *E. cloacae* and *C. freundii* isolated were fully resistant to Norfloxacin and of Ofloxacin. For the 3 Sulfonamides+trimethoprim, all strains of *C. freundii* and *S. typhi* isolated were resistant to Nurofurantoin and Fosfomycin. Most of bacteria strains isolated in wastewater and surface water were resistant to all the antibiotics tested. Many bacterial strains tested were multi-resistant. This multidrug resistance was more marked in *E. cloacae* and *C. freundii* species isolated from wastewater and surface water. This represents a health risk for humans and the aquatic environment.

1. Introduction

A significant proportion of bacteria isolated in freshwater are of the Enterobacteriaceae family. Their abundance in the intestine, their mobility and the frequent acquisition of antibiotic resistance mechanisms explain why they are the most involved bacteria in human infectious pathology [1]. Most effluents from municipal, industrial, veterinary activities, hospital and secondary treatment sources harbored enterobacteria [2, 3]. These discharges often lead to the contamination of natural aquatic environments [4, 5]. In addition, antibiotics and their metabolites released have a direct impact on microorganisms in the environment [6-8].

Antibiotics can be classified on the basis of their mechanisms of action and the mechanisms of antimicrobial resistance, although the resistance mechanism of individual antibiotics has been indicated [9-11]. Based on the mechanisms of their action, they can be grouped into antibiotics targeting cell wall, inhibitors of protein biosynthesis, inhibitors of DNA replication and folic acid metabolism inhibitors. Based on the mechanisms of antimicrobial resistance, there are two main ways: antibiotic inactivation and the prevention of accumulation of antimicrobials either by decreasing uptake or increasing efflux of the antimicrobial from the cell i.e., changes in outer membrane permeability.

According to Li et al. [12], the efficacy of antimicrobials in general is influenced by many factors including: a)-the bacterial status (susceptibility and resistance, tolerance, persistence, biofilm) and inoculum size; b)-the antimicrobial concentrations [mutant selection window and sub-inhibitory concentration]; c)-the host factors. Bacterial status is one of the determinants for antimicrobial activity. Bacterial phenotypes are different under antibiotic exposure, such as susceptibility, resistance, tolerance, and persistence [13]. Antibiotic resistance happens when germs develop the ability to defeat the drugs designed to kill them. This does not mean the body is becoming resistant to antibiotics; it is that bacteria have become resistant to the antibiotics. The germs are not killed and continue to grow. This phenomenon has the potential to affect people at any stage of life, making it one of the world's most urgent public health problems [14]. Several works conducted on the resistant profile of bacteria isolated from hospital environments and belonging to the Enterobacteriaceae family are resistant to different families of antibiotics [15].

The origins of antibiotic resistance could be the result of genetic juggling during which random mutations of the genes encoding the enzymes can give rise to modified catalysts with increasingly extended spectra of resistance and intrinsic resistance which refers to the existence of genes in bacterial genomes that could generate a resistance phenotype [16, 17]. Other origin is from resistosome. This refers to all the antibiotic resistance genes in communities of both pathogenic and non-pathogenic bacteria or all of the resistance genes in an organism, how they are inherited, and how their transcription levels vary to defend against pathogens like viruses and bacteria [18-20]. For this, bacterial strains resistant to antibiotics can be isolated by plating environmental bacteria on antibiotic-containing media since most possess genes encoding resistance to the compounds that they produce [21]. Bacteria can thus be naturally resistant to particular antibiotics; others, however, develop resistance through genetic mutations induced via exposure to antibiotics. Antibiotic resistance also has the opportunity to spread, given the ease of exchanging the material relating to resistance between bacterial species [22]. Antibiotic resistance genes isolated are usually not present in pathogenic bacteria, nor do they appear in the antibiotic era, but rather originate from antibiotic-producing microbes or those that cohabit with them in the environment [23].

Enterobacteriaceae are enzyme producers and possess other mechanisms of resistance to many antibiotics [24, 25]. The high concentration of these germs in the gastrointestinal tract favours the exchange and dissemination of resistant genes in the environment [26, 27], particularly in domestic and hospital wastewater, and sometimes even in groundwater and surface water. In these different water systems, antibiotic susceptibility of bacteria can be impacted by many environmental factors [28, 29].

Each year, waterborne diseases afflict hundreds of millions of people, primarily those living without safe, accessible water in developing countries. Waterborne diseases are illnesses caused by microscopic organisms that are ingested through contaminated water or by coming in contact with feces, with diarrhea as the central symptom [30]. Some of the waterborne pathogens are ubiquitous [31]. Most of the concerned bacteria belongs to the Enterobacteriaceae family [32, 33]. The situation is aggravated by the rise of antimicrobial resistant bacteria which has been identified as one of the biggest global health challenges [34].

Few studies have been done on the antibiotic susceptibility profile of Enterobacteriaceae species from different types of hydrosystems in the same geographical area. The present study aims to make a comparative approach of the sensitivity/resistance to antibiotics of 4 Enterobacteriaceae *Enterobacter cloacae*, *Citrobacter freundii*, *Salmonella typhi* and *Shigella sonnei* isolated from wastewater, streams and groundwater of Yaounde town (Cameroon, Central Africa).

2. Material and methods

2.1. Study area

Yaounde which is the capital of Cameroon. It is located 300 km from the Atlantic coast, between 3°5' North latitude and 11°31' East longitude [35]. The climate is equatorial, characterised by the alternation of two dry seasons and two rainy seasons: a long dry season from December to mid-March, a short rainy season from mid-March to June, a short dry season from July to August and a long rainy season from September to November. The annual average temperature is 23.5°C, varying between 16 and 31°C depending on the season, and 1650 mm of water per year. The city's hydrographic network is very dense and essentially composed of the Mfoundi river and its tributaries. Some districts and hospitals in Yaounde are equipped with wastewater treatment plants. The study was conducted in November 2020 (during the long rainy season).

2.2. Sampling sites and water sampling

Four kinds of sampling sites have been chosen: wastewater of the University Hospital Centre (UHC), wastewater from residential quarters, surface water, and groundwater. The wastewater of the UHC included wastewater collector of the UHC laundry room coded Sw1, wastewater collector of the surgical room of the UHC coded Sw2, and wastewater from the laundry and the surgery room of the UHC coded Sw3.

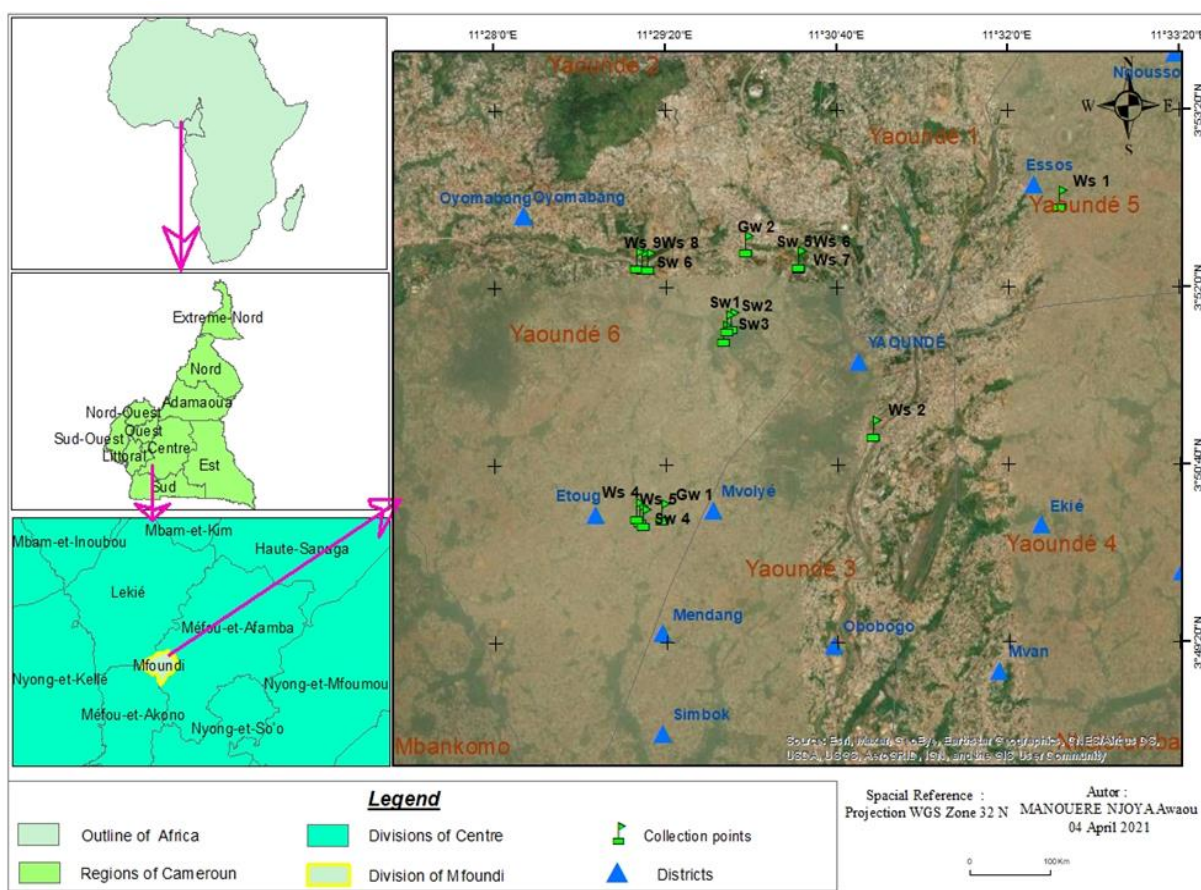

Figure 1 Geographical location of the study area and representation of the sampling points Sampling

(Source: https://d-maps.com/pays.php?num_pay=16&lang=fr)

The wastewater from residential quarters included that from Biyem-Assi quarter wastewater treatment plant coded Sw4, that from Massa quarter wastewater treatment plant coded Sw5, and that from Cité Verte quarter wastewater treatment plant coded Sw6. The three wastewater treatment plants are waste stabilization ponds. The surface water included 9 sampling points: upstream, landing and downstream of the Mfoundi river coded Ws1, Ws2 and Ws3 respectively.

Table 1 Characteristics of sampling points

Hydro-systems	Sampling station	Geographical coordinates		Description
		Latitude (N)	Longitude (E)	
Hospital waste-water (Sw)	Sw1	3°86'25,82"	11°49'74,88"	Waste water collector of the UHC laundry room
	Sw2	3°86'22,25"	11°49'69,86"	Wastewater collector of the surgical room of the University Hospital
	Sw3	3°86'09,47"	11°49'49,6"	Collector receiving wastewater from the laundry and the surgery room of the University Hospital
Domestic waste-water (Sw)	Sw4	3°83'83,33"	11°48'56,23"	Wastewater discharge point of the Biyem-Assi wastewater treatment plant
	Sw5	3°87'02,12"	11°50'63,2"	Wastewater discharge point of the Messa wastewater treatment plant
	Sw6	3°87'00,3"	11°48'59,16"	Wastewater discharge point of the Cité Verte wastewater treatment plant
Surface water (Ws)	Ws1	3°87'77,22"	11°54'01,3"	Upstream of the Mfoundi river, close to houses and where domestic waste is dumped
	Ws2	3°84'90,11"	11°51'59,68"	Landing on the Mfoundi river, receiving domestic waste
	Ws3	3°80'36,78"	11°50'93,25"	Downstream of the Mfoundi river, near a brewery company
	Ws4	3°83'87,69"	11°48'50,98"	Upstream of the Biyeme tributary which receives wastewater from the Biyem-Assi wastewater treatment plant
	Ws5	3°83'78,86"	11°48'60,18"	Downstream of the Biyeme tributary which receives wastewater from the Biyem-Assi wastewater treatment plant
	Ws6	3°87'02,55"	11°50'62,68"	Upstream of the Mingoa tributary which receives wastewater from the Messa wastewater treatment plant
	Ws7	3°87'01,94"	11°50'63,4"	Downstream of the Mingoa tributary which receives wastewater from the Messa wastewater treatment plant
	Ws8	3°87'00,83"	11°48'66,31"	Upstream of the Abiergué tributary which receives wastewater from the Cité Verte plant
	Ws9	3°87'01,42"	11°48'52,98"	Downstream of the Abiergué tributary which receives wastewater from the Cité Verte plant
Ground-water (Gw)	Gw1	3°83'85,53"	11°48'85,19"	Covered well located near the Biyem-Assi wastewater treatment plant and houses
	Gw2	3°87'20,89"	11°49'94,01"	Developed spring located upstream of the Mingoa tributary

The Biyeme tributary upstream coded Ws4 and downstream coded Ws5, the Mingoa tributary upstream coded Ws6 and downstream coded Ws7, and the Abiergue tributary upstream coded Ws8 and downstream coded Ws9 were also

included. The groundwater sampling points included one wells coded Gw1 and one springs coded Gw2. In total, 17 sampling sites were chosen for this study. They are presented in Figure 1 and their characteristics and geographic coordinates are indicated in Table 1.

Water sampling was performed according to the method of Rodier et al. [36]. For the physicochemical analyses, the samples were collected in 1000 mL polyethylene bottles previously rinsed with the sample water; while the samples for bacteriological analyses, around 300 mL were collected in 500 mL sterile glass bottles. The samples were then brought back to the laboratory in a refrigerated chamber (4°C) for analysis.

2.3. Physicochemical analysis

Physicochemical parameters were analyzed according to the techniques recommended by Rodier et al. [36] and APHA [37]. The parameters considered for this study were: temperature, pH, electrical conductivity, nitrates and orthophosphates. Temperature, pH and electrical conductivity were measured in the field using a HANNA/HI 9829 multimeter; while nitrates and orthophosphates were measured in the laboratory using a DR/2000 HACH spectrophotometer.

2.4. Bacteriological analysis

2.4.1. Isolation of Heterotrophic aerobic bacteria (HAB) and Enterobacteriaceae

Heterotrophic aerobic bacteria (HAB) were isolated on standard plate count agar. The isolation and counting of the total Enterobacteriaceae were performed on *Drigalski* Lactose agar culture medium [38]. The agar culture medium Methylene Blue Eosin (EMB) (Biokar) was used for the isolation of *Enterobacter cloacae* and *Citrobacter freundii* [39, 40] and the agar culture medium Salmonella-Shigella (SS) (Biokar) was used for the isolation of *Salmonella typhi* and *Shigella sonnei* [41-43]. Plate count technique was used. A volume of 0.1 mL of each sample or after dilution was taken with a micropipette and plated on the surface of the agar contained in Petri dishes. Incubation was done at laboratory temperature (25°C ± 2°C) for 5 days HAB, and at 37°C for 24 hours for others [36, 43]. All the analyses were done in triplicate.

2.4.2. Macroscopic examination and identification of Enterobacteriaceae species

After the incubation period, colonies were counted in the different Petri dishes based on their characteristics. On EMB culture medium, *Enterobacter* will appear pink-colored colonies without a sheen whereas *Citrobacter* will appear brown colored colonies without any metallic sheen [39, 40]. On the SS culture medium *Salmonella* will not ferment lactose, but produce hydrogen sulfide (H₂S) gas, and their colonies will appear colorless with black centers, whereas *Shigella* do not ferment lactose or produce hydrogen sulfide gas, and their colonies will be colorless [41-43]. After enumeration of the colony forming units based on the cultural characteristics of the bacteria, the cells of each colony were recultured on standard (non-selective) agar, this agar having been solidified in the sloping test tubes. After Gram coloration, biochemical tests were then performed using the API 20 E systems (Biomerieux) [44].

2.4.3. Antibigram tests

The antibiogram tests were done by the diffusion method of antibiotic discs on Muller Hinton medium according to the recommendations of the "Antibiogram Committee of the French Microbiology Society" (AC-FMS) [45]. Antibiotic molecules were chosen according to their sensitivity and/or resistance to Enterobacteriaceae, but also according to their availability in the market.

A total of 20 antibiotic molecules belonging to four families were used in the susceptibility testing galleries. The family of β-lactams (Amoxicillin; Amoxicillin + Clavulanic acid; Imipenem; Meropenem; Ticarcillin; Piperacillin; Piperacillin/tazobactam; Ceftriaxon; Cefepim; Cefuroxim; Cefoxitim; Ceftazidim), the family of Quinolones (Ciprofloxacin; Norfloxacin; Ofloxacin), the family of Aminoglycosides (Amikacin; Gentamycin), and the family of Sulfonamides+Trimethoprim and others (Trimethoprim/Sulfamethoxazole; Nurofurantoin; Fosfomycin).

Inhibition diameters were measured using the caliper and the results were scored as either resistant, sensitive or intermediate according to the interpretation of CA-SFM [46, 47].

2.5. Data analysis

The abundances of the bacteria isolated were expressed per volume of 100 ml of water. The values of physicochemical parameters and those of bacterial abundances were illustrated by histograms plotted using Excel 2016 software. The

Kruskal-Wallis and Mann-Whitney tests were carried out using SPSS software version 25.0 to compare the inhibition diameters of antibiotic against bacterial species in each types of water.

3. Results and discussion

3.1. Physicochemical parameters

Figure 2 Variation of physicochemical parameters in the different sampling points (A: variation of temperature and pH; B: variation of electrical conductivity; C: variation of the concentration in nitrates and orthophosphates)

The mean values of the physicochemical parameters are represented on Fig.2. It appears that these parameters values varied from one point to another. The temperature values varied between 22.8 and 26.2°C, with the lowest value recorded at the surface water station Ws5 and the highest value at station Ws3 (Fig. 2A). This variation is much more pronounced in surface water than in wastewater and groundwater and this could be explained by variations in the ambient temperature of the environment. According to Merhabi et al. [48], the temperature of surface water is affected by fluctuations in precipitation and seasonal temperatures. Wastewater temperature depends on organic load while groundwater temperature depends on latitude and altitude. Water temperature is an important factor as it governs almost all physicochemical and biological reactions. An abrupt change in this parameter leads to the disturbance of the water ecosystem balance [49]. The pH values ranged from 6.3 to 8.2 C.U. with the lowest value recorded in springs Gw2 and the highest wastewater station Sw6 (Fig. 2A). It is observed that pH of the sampled groundwater is slightly acidic while that of the wastewater and surface water is slightly basic. This has also been noted by Diane et al. [50]. According to Noah et al. [51], pH between 6.0 and 8.5 U.C. is favorable for the expression of biological potentials of several groups.

Electrical conductivity fluctuated between 41 and 810 $\mu\text{S}/\text{cm}$ with the lowest value recorded at the surface water station Ws9 and the highest at stations Sw4 and Sw6 (Fig. 2B). The nitrate content fluctuated from point to point between 5.4 and 37.4 mg/L. The lowest value was recorded at station Ws7 while the highest is recorded in wells Gw1 (Fig. 2C). Regarding orthophosphate content, the values varied between 1.56 and 5.29 mg/L with the lowest value recorded at wastewater station Sw3 and the highest at surface water station Ws8 (Fig. 2C). According to Rodier et al. [36], the presence of phosphates in natural waters is linked to the nature of the terrain crossed, the decomposition of organic matter and the use of detergents. As organic pollution is noticeable when the orthophosphate content is higher than 0.5 mg/L, these waters are polluted [36].

3.2. Bacterial abundance

The variation in the abundance of heterotrophic aerobe bacteria (HAB) and Enterobacteriaceae is presented in Fig. 3. In wastewaters samples from the University Hospital Centre (UHC), the abundance of heterotrophic aerobe bacteria (HAB) varied from 18.4×10^3 to 463×10^3 CFU/100 μL and that of Enterobacteriaceae varied from 0.95×10^3 to 20.8×10^3 CFU/100 μL . For the wastewaters from the residential quarters, the abundance of heterotrophic aerobe bacteria (HAB) varied from 60.4×10^3 to 212×10^3 CFU/100 μL and that of Enterobacteriaceae varied from 0.5×10^3 to 17.8×10^3 CFU/100 μL . In the surface waters, they varied from 144×10^3 to 401×10^3 CFU/100 μL for HAB and from 6.5×10^3 to 38×10^3 CFU/100 μL for Enterobacteriaceae. In groundwater sampled, abundance of HAB varied from 4.7×10^3 to 12×10^3 CFU/100 μL for HAE and from 0.3×10^3 to 0.6×10^3 for the Enterobacteriaceae (Fig. 3).

Figure 3 Variation with respect to the sampling sites of the abundance of the total heterotrophic aerobe bacteria (HAB) and Enterobacteriaceae

The mean values of the abundance of cells species are presented on Fig. 4. It is noted *E. cloacae* abundance fluctuated between 1 CFU/100 μ L and 30 CFU/100 μ L. The lowest value recorded in springs Gw2 and the highest at wastewater station Sw5 (Fig. 4). For *C. freundii*, its abundance varied between 1 CFU/100 μ L and 112 CFU/100 μ L. The lowest value was recorded in springs Gw2 and the highest at surface water station Ws8 (Fig. 4). The abundance of *S. sonnei* ranged from 2 CFU/100 μ L to 198 CFU/100 μ L. The lowest value was recorded in the springs Gw2 and the highest value at the surface water station Ws2 (Fig. 4). For *S. typhi*, the abundance ranged from 1 CFU/100 μ L to 44 CFU/100 μ L. The lowest value was recorded in GW1 and wastewater station Sw3 and the highest at station Sw5 (Fig. 4).

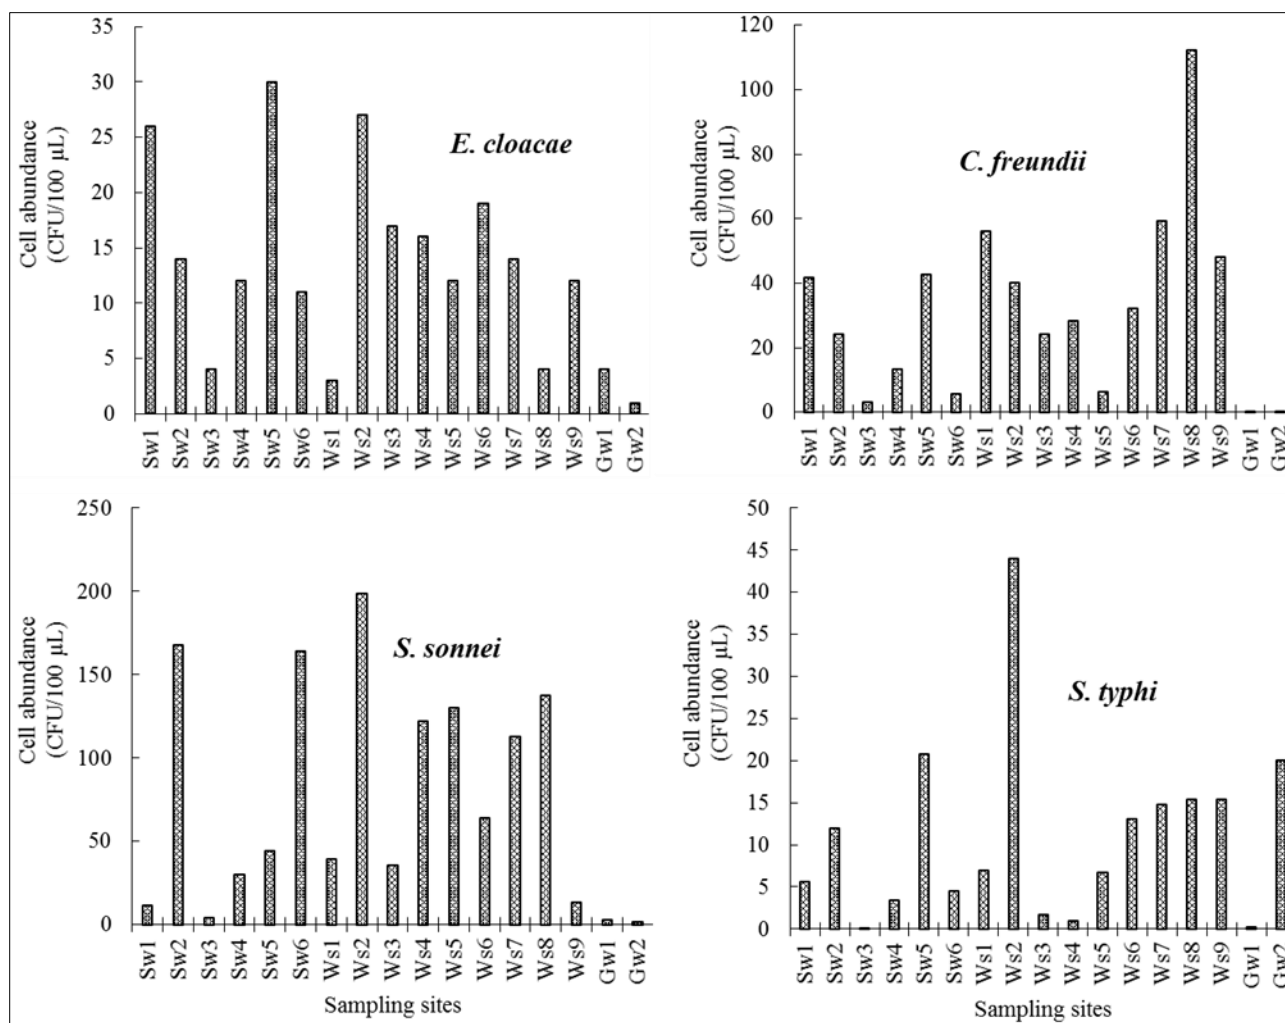

Figure 4 Abundance of Enterobacteriaceae species (*E. cloacae*, *C. freundii*, *S. sonnei* and *S. typhi*) isolated in the different sampling points

The presence of these Enterobacteriaceae in the different sampling stations indicate faecal pollution as these species are generally isolated in the stools and urine of people with severe pathologies. The composition of these ecosystems reflects the characteristics of bacteria released by humans, mainly in faeces [52]. Among the isolated Enterobacteriaceae, the species *S. sonnei* had the highest abundance (198 CFU/100 μ L) amongst all type of water sampled. This may be related to their ability to multiply more rapidly on one hand, and to the presence of environmental factors favourable to their growth on the other hand. According to Chloé [53], the *Shigella* species are of higher relative frequency in the environment than in human faeces and urine.

3.3. Antibiotic susceptibility to the considered Enterobacteriaceae

3.3.1. Inhibition diameters

The diameters of inhibition of the antibiotics varied according to the tested bacterial species and the type of water where it was isolated (Table 2). No inhibition diameter was observed against Ciprofloxacin, Ticarcillin, Piperacillin/tazobactam, Norfloxacin, Fosfomycin, Gentamycin, Ofloxacin, Amoxicillin+clavulanic acid and

Sulphamethazole/trimethoprim in the presence of *E. cloacae* species isolated from groundwater. Ticarcillin does not show any inhibition diameter against *C. freundii* species isolated in surface water. However, when this species was isolated in groundwater, the same result was noted in the presence of Amoxicillin, Ticarcillin, Piperacillin/tazobactam, Cefepim, Fosfomycin, Cefuroxim and Sulphamethazole/trimethoprim (Table 2). For *S. sonnei* isolated from groundwater, no inhibition diameter was noted in the presence of Sulphamethazole/trimethoprim, Cefuroxim, Amoxicillin+clavulanic acid, Ofloxacin, Gentamycin, Fosfomycin, Ticarcillin and Piperacillin/tazobactam (Table 2). The same was noted for *S. typhi* isolated from surface water in the presence of Ticarcillin and Piperacillin/tazobactam, and also from groundwater in the presence of Piperacillin/tazobactam, Piperacillin, Fosfomycin, Gentamycin, Cefoxitim, Cefuroxim and Sulphamethazole/trimethoprim (Table 2).

However, it should be noted that some antibiotics have presented the greatest diameters of inhibition to bacterial species depending on the type of water where they are isolated. Against the species isolated in wastewater, the antibiotics with a larger diameter of inhibition are: Imipenem (14.33 mm) in the presence of *E. cloacae*; Sulphamethazole/trimethoprim (19.7 mm) in the presence of *S. sonnei*; and Gentamycin (17.17 mm) in the presence of *S. typhi* (Table 2). For species isolated from groundwater, there are Ceftriaxon (24.50 mm), Gentamycin (23 mm) and Amikacin (22 mm) in the presence of *C. freundii*; and Imipenem (16.50 mm) in the presence of *S. sonnei* (Table 2). With respect to the cells species isolated from surface water, there are Imipenem (18.78 mm) in the presence of *C. freundii*; and Amikacin (17.67 mm) in the presence of *S. sonnei* (Table 2).

Table 2 Different inhibition diameters of each antibiotic with the different types of water for each bacterial species (resistance (R), intermediate (I) and sensitive (S))

Values represent mean value ±standard deviation of inhibition diameter of each antibiotic used (mm) for *E. cloacae* and *C. freundii* (A); and for *S. sonnei* and *S. typhi* (B). R: Resistant; S: sensitive; AX: Amoxicillin; MEM: Meropenem; CIP: Ciprofloxacin; TIC: Ticarcillin; TPZ: Piperacillin/Tazobactam; F: Nurofurantoin; CRO: Ceftriaxon; NOR: Norfloxacin; PRL: Piperacillin; FEP: Cefepim; FF: Fosfomycin; CN: Gentamycin; FOX: Cefoxitim; OFX: Ofloxacin; AMC: Amoxicillin+clavulanic acid; AK: Amikacin; CXM: Cefuroxim; CAZ: Ceftazidim; IMI: Imipenem; SXT: Sulfamethazole/trimethoprim

All the cells tests were harvest from the stationary growth phase. The differences noted in the inhibition diameters could not be linked to specific the metabolism to the strain of each bacterial species. Main relation exists between the bacterial metabolism and the antibiotic activity. Stokes et al. [54] describe three postulates that collectively define antibiotic efficacy in the context of bacterial metabolism: a)-antibiotics alter the metabolic state of bacteria, which contributes to the resulting death or stasis; b)-the metabolic state of bacteria influences their susceptibility to antibiotics; and c)-antibiotic efficacy can be enhanced by altering the metabolic state of bacteria.

The bacterium strains *C. cloacae* isolated from the groundwater is the only which appeared sensitive against 3 of the antibiotics tested, including one β -Lactam (Ceftriaxon) and 2 quinolones (Amikacin and Gentamycin). All the bacteria strains isolated in wastewater and surface water were resistant to all the antibiotics tested (Table 2). Environment is a vast source of new and emerging resistance genes, due to the links sometimes between the environment and gene mobilization [55, 56]. The acquisition of genes in water habitats and the development of antibiotic resistances can occur. According to Lupu et al. [57], the acquisition of heterologous genes by lateral transfer largely facilitates the adaptive evolution of bacteria, especially under strong selective pressures. This transfer of exogenous DNA in bacteria may be mediated by plasmids, phages, transposons, genomic islands, or captation of free DNA by transformation [57]. Sengelov and Sorensen [58] indicated that in many kinds of water, plasmid transfer from a donor to a recipient cell occur, even at a low frequency, and several factors could, not only influence, but also promote gene transfer among bacteria in water environment [59].

3.3.2. Percentage of cells inhibition

Antimicrobial susceptibility testing showed high resistance (74.51%) of isolated Enterobacteriaceae (*E. cloacae*, *C. freundii*, *S. sonnei* and *S. typhi*) against several antibiotics that have been used. This resistance varied from one antibiotic family to another and this was observed through the percentages of inhibition (Table 3). According to Pierre [60], Enterobacteriaceae are the bacteria that are multi-resistant to antibiotics.

In the β -lactam family which represents 60% of antibiotics used in medicine [61] all strains of isolated *E. cloacae* at the 17 sites were fully resistant to 8 antibiotics. The *C. freundii* strains were fully resistant to 8 antibiotics tested and sensitive to one (Ceftriaxon). *S. sonnei* were fully resistant to 8 antibiotics and sensitive to one (Ceftazidim). With *S. typhi*, isolated strains were fully resistant to 6 antibiotics and sensitive to two (Meropenem and Ceftazidim) (Table 3).

The low toxicity of β -lactams and the broad spectrum of action of some of them make β -lactams the most prescribed antibiotic drug class and propagation of resistance constitutes therefore a major clinical concern. It has been indicated that the bacterial resistance against β -lactams is related to the usage of the drug in clinics, both because of selection of resistant bacteria and by promoting the mobilization of the genes responsible for such resistances [62]. Similarly, the presence of antibiotics in some water environments could promote the selection of antibiotic resistant strains [63].

According to Sophie [64], Enterobacteriaceae are naturally resistant to β -lactam antibiotics because they produce β -lactamases to inhibit antibiotic; this would explain the high percentage of resistance obtained. The sensitivity rate recorded with Ceftazidim and Cefuroxim antibiotics (32% and 17.8%) would be due to the fact that the resistance mechanism of *S. typhi* and *S. sonnei* is acquired and therefore these species inhibit the antibiotics very little.

For the 2 aminoglycosids tested, 5.88% of the strains of each isolated species were resistant to gentamycin. 88.24% of *E. cloacae* and *S. sonnei* strains, 94.12% of *C. freundii* and *S. typhi* were sensitive to this antibiotic. The proportion of sensitive and resistant strains towards the Amikacin also varied (Table 3). The aminoglycosides primarily act by binding to the aminoacyl site of 16S ribosomal RNA within the 30S ribosomal subunit, leading to misreading of the genetic code and inhibition of translocation. They inhibit protein synthesis and contain as a portion of the molecule an amino-modified glycoside [11, 65]. The aminoglycoside modifying enzymes produced by the bacteria would have reduced affinity of aminoglycoside molecule, impede binding to the 30S ribosomal subunit, and provide extended spectrum resistance to aminoglycosides [11, 66]. Aminoglycosides are antibiotics that are naturally sensitive to Enterobacteriaceae [60], which explains the high sensitivity rate obtained.

Of the 3 quinolones tested, all strains of *E. cloacae* and *C. freundii* isolated from the 17 sites were fully resistant to Norfloxacin and of Ofloxacin. The proportion of strains of the 4 isolated species and which were sensitive to quinolones varied between 5.88 and 24.54% (Tables 3). The antibiotic that showed slight sensitivity in all species was Ciprofloxacin. Gaudreau et al. [67] showed that Enterobacteriaceae, specifically *Shigella* develop resistance to quinolones. Rodriguez-Martinez et al. [68] indicated that one of the fluoroquinolones resistance genes are of the *qnr* family. *qnr* genes encode proteins binding the bacterial DNA gyrase, thus preventing the interaction of the antibiotic with its target. Generally, the presence of these acquired genes does not confer a high level of fluoroquinolones resistance, but provides a selective

advantage in the presence of these drugs, even at low concentrations [68]. Another acquired fluoroquinolones resistance mechanism is represented by efflux mechanisms in which the *qepA* gene, encodes efflux pump [25, 69]. It has been recovered from the metagenome of river sediments impacted by wastewaters [70]. According to Sophie [64], the decrease in susceptibility is due to the decrease in permeability and enzymatic inactivation; this could explain the low rate of susceptibility to quinolones observed.

AX: Amoxicillin; MEM: Meropenem; CIP: Ciprofloxacin; TIC: Ticarcillin; TPZ: Piperacillin/Tazobactam; F: Nurofurantoin; CRO: Ceftriaxone; NOR: Norfloxacin; PRL: Piperacillin; FEP: Cefepim; FF: Fosfomycin; CN: Gentamycin; FOX: Cefoxitim; OFX: Ofloxacin; AMC: Amoxicillin+clavulanic acid; AK: Amikacin; CXM: Cefuroxim; CAZ: Ceftazidim; IMI: Imipenem; SXT: Sulfamethazole/trimethoprim

For the 3 Sulfonamides+Trimethoprim tested, all strains of *C. freundii* and *S. typhi* isolated were resistant to Nurofurantoin and Fosfomycin. The proportion of resistant *E. cloacae* and *S. sonnei* strains was 88.24% and 94.11 respectively against Nurofurantoin, and 88.24 and 82.35% against Fosfomycin (Table 3). The proportion of strains sensitive to one of the 3 antibiotics of this family varied from 11.76 to 23.54% for *E. cloacae*, from 0 to 17.64% for *C. freundii*, from 5.89 to 17.65% for *S. sonnei* and from 0 to 11.76% for *S. typhi* (Table 3). Sensitivity was noted in Sulfamethazole/trimethoprim against all species (Table 3). Sulfonamides are the antibiotics to which bacteria are generally sensitive; however, in this study there was a high level of resistance. The target of sulfonamides in bacteria is

the enzyme dihydropteroate synthase. It is involved in the bacterial synthesis of the vital coenzyme, folic acid. Sulphonamides compete with the normal substrate of the enzyme, *p*-aminobenzoic acid, at the formation of dihydropteroate, which after the addition of glutamic acid gives folic acid [71]. The decrease in membrane permeability or to the acquisition of resistant plasmids or transposons could contribute to the loss of sensitivity [28].

Many mechanisms that bacteria exhibit to protect themselves from antibiotics can be classified into four basic types [56, 57, 72]: a)-the antibiotic modification, b)-the protection of the target of antibiotic action by preventing the antibiotic from entering the cell or pumping it out faster than it can flow in, c)-the alterations in the primary site of action, and d)-the production of an alternative target (usually an enzyme) that is resistant to inhibition by the antibiotic.

Multidrug-resistance has been noted in this study (Tables 2 and 3). It is known that environmental microorganisms can become multidrug-resistant. Bacteria are unique in that they acquire genes from the parent microorganism during division (vertical gene transfer), but can also acquire genes from the community at large (horizontal gene transfer) [73, 74].

3.3.3. Comparison of the inhibition diameters of antibiotics

The Kruskal-Wallis test was performed to compare inhibition diameters of each antibiotic of the bacterial species isolated in all the considered types of water.

Table 4 P-values of the Kruskal-Wallis test comparing the antibiotics inhibition diameters amongst bacterial species isolated in all the types of water sampled

SXT (25)	0.250	0.151	0.008**	0.203

*: $P < 0.05$; **: $P < 0.01$; AX: Amoxicillin; MEM: Meropenem; CIP: Ciprofloxacin; TIC: Ticarcillin; TPZ: Piperacillin/Tazobactam; F: Nurofurantoin; CRO: Ceftriaxon; NOR: Norfloxacin; PRL: Piperacillin; FEP: Cefepim; FF: Fosfomycin; CN: Gentamycin; FOX: Cefoxitim; OFX: Ofloxacin; AMC: Amoxicillin+clavulanic acid; AK: Amikacin; CXM: Cefuroxim; CAZ: Ceftazidim; IMI: Imipenem; SXT: Sulfamethazole/trimethoprim

It is noted a significant difference ($P < 0.05$) of the inhibition diameters of the antibiotics Imipenem and Amoxicillin+clavulanic acid for *E. cloacae*, Ticarcillin and Cefoxitim for *C. freundii*, Amoxicillin, Fosfomycin, Cefuroxim, Ceftazidim and Sulfamethazole/trimethoprim for *S. sonnei*, and Gentamycin for *S. typhi* (Table 4).

The U test of Mann-Whitney was performed to compare the antibiotic inhibition diameters of bacterial species isolated between different types of water taken 2 by two, against the 9 antibiotics that stood out from the Kruskal test. The result is presented in Table 5. It is noted a significant difference ($P < 0.05$) between the inhibition diameters of Imipenem for *E. cloacae* isolated in surface water and groundwater on one hand, and in wastewater and groundwater on the other hand. The same observation was also made between the inhibition diameters of Amoxicillin+acid clavulanic for this bacterium when isolated in wastewater and groundwater (Table 5). A difference in the behavior of *C. freundii* strains isolated from wastewater and groundwater, as well as from surface water and wastewater, was observed with respect to Ticarcillin and Cefoxitin, respectively (Table 5). Likewise, a difference in susceptibility of the *S. sonnei* and *S. typhi* strains depending on the biotopes is also noted with respect to Amoxicillin, Fosfomycin, Cefuroxim, Cefazidim and Sulfamethoxazole/trimethoprim on the one hand, and Gentamycin on the other hand (Table 5).

Significant differences ($P < 0.05$) in the antibiotics susceptibility appeared for 7 antibiotics between bacterial strains isolated from wastewater and those from groundwater, for 6 antibiotics between bacterial strains isolated from surface water and those from wastewater, and for 3 antibiotics between bacterial strains isolated from surface water and those from groundwater (Table 5). Most strains isolated from groundwater respond to antibiotics differently from those isolated from wastewater. The difference observed in the bacterial susceptibility against antibiotics with respect to the type of water could be linked to the abiotic properties of the water medium. Signe et al. [75] noted some significant correlations between some physico-chemical characteristics of water and the inhibition diameters of antibiotics. Eshet et al. [29] noted that the pH of the water medium harboring bacterial cell significantly impacts on their antimicrobial susceptibility. It has thus been suggested that the regulation of some bacterial genes would be regulated by complex mechanisms including interactions of some abiotic water characteristics [29, 75].

In addition, the astounding number of bacterial cells in the water systems provide an immense genetic variability, and opportunities for mutations, rearrangements and horizontal gene transfer. Thus, new resistance factors likely appear regularly. Resistance factors are generally associated with some fitness cost. This cost may be particularly large for genes providing novel resistance functions for a bacterium, as their expression may not be sufficiently fine-tuned and

their products may interfere with other cellular functions. Thus, novel resistance genes will be selected against unless there is a relatively strong selection pressure to maintain them [76, 77].

4. Conclusion

The Enterobacteriaceae *E. cloacae*, *C. freundii*, *S. sonnei* and *S. typhi* isolated from waster, surface water and groundwater in the Yaounde town are resistant to β -lactams, quinolones and sulfonamides, and sensitive to aminoglycosides. The inhibition diameters of antibiotic and the bacterial susceptibility against antibiotics with respect to the type of water. The susceptibility to antibiotics of Enterobacteriaceae may be linked to a complex mechanism and would be impacted by many factors. This may include the cells intrinsic properties as well as the characteristics of the environment harboring them. The regulation of some bacterial genes acting against antibiotics would be controlled by complex mechanisms including interactions of some abiotic water characteristics. It appears that the multiple uses of antibiotics in hospitals and probably in human communities can cause multidrug resistance for bacteria. This represents a health risk for humans and the aquatic environment. A control should be established in their use in hospitals and in homes, as well as tertiary treatment at the outlet of wastewater treatment plants.

Compliance with ethical standards

Acknowledgments

A Manouore Njoya, Y Poutoum and EB Mouafo Tamnou carried out the water sampling in the field. CS Metsopkeng, JS Heth, OV Noah Ewoti, A Tamsa Arfao and LM MOUNGANG carried out physicochemical and bacteriological analysis as well as data analysis. S Chinche Belengfe improved the english language of the manuscript. PA Nana, E Masseret and T Sime-Ngando supplied some reagents and laboratory equipment and were also involved in the manuscript writing. All the study was supervised by M Nola.

Disclosure of conflict of interest

None conflict of interest to declare. The manuscript has not been previously submitted or published in other journal and is not being considered for publication elsewhere.
