Abstract :

Stress hormones and their impacts on whole organism metabolic rates are usually considered as appropriate proxies for animal energy budget that is the foundation of numerous concepts and models aiming at predicting individual and population responses to environmental stress. However, the dynamics of energy re-allocation under stress make the link between metabolism and corticosterone complex and still unclear. Using ectopic application of corticosterone for 3, 11 and 21 days, we estimated a time effect of stress in a lizard (Zootoca vivipara). We then investigated whole organism metabolism, muscle cellular O2 consumption and liver mitochondrial oxidative phosphorylation processes (O2 consumption and ATP production) and ROS production. The data showed that while skeletal muscle is not impacted, stress regulates the liver mitochondrial functionality in a time-dependent manner with opposing pictures between the different time expositions to corticosterone. While 3 days exposition is characterized by lower ATP synthesis rate and high H2O2 release with no change in the rate of oxygen consumption, the 11 days exposition reduced all three fluxes of about 50%. Oxidative phosphorylation capacities in liver mitochondria of lizard treated with corticosterone for 21 days was similar to the hepatic mitochondrial capacities in lizards that received no corticosterone treatment but with 40% decrease in H2O2 production. This new mitochondrial functioning allows a better capacity to respond to the energetic demands imposed by the environment but do not influence whole organism metabolism. In conclusion, global mitochondrial functioning has to be considered to better understand the proximal causes of the energy budget under stressful periods.

Introduction

Glucocorticoids (GCs) secreted by the hypothalamus–pituitary–adrenal axis are crucial hormones orchestrating the tradeoff between survival and different physiological processes when vertebrates are facing stressors. However, physiological consequences are known to be different in accordance to short-term versus long-term elevations in GCs production. While many of the acute effects of GCs consist of mobilizing energy, chronically elevated circulating GCs enhance energy storage (Harris 2015, Sapolsky et al. 2000). Similarly, acute GC elevations can activate the adaptive immune system, whereas chronic GC elevations are linked to suppressed cell-mediated leucocyte trafficking (Sorrells et al. 2009; Dhabhar and Mc Ewen 1997). Such biphasic responses in which acute and chronic stress or corticosteroid exposure induce contrasting and sometimes opposite effects have not yet been fully elucidated. While some studies stipulate potential differential actions of different nuclear receptors of GCs (e.g., Joels and de Kloet 1992), others link it to larger magnitude changes in gene expression under acute stress rather than chronic stress (e.g., Wang et al. 2004).

Other studies demonstrated rapid, non-genomic effects of GCs (de Kloet, 2013) explained at least partly by the GCs translocation to the mitochondria that provide ATP through the Krebs tricarboxylic-acid cycle and oxidative phosphorylation (Du, 2009, Lee et al. 2013). Indeed, *in vitro* (with cortical neuronal cultures) and *in vivo* (with brains from male rats) experiments have demonstrated that mitochondrial oxidation, membrane potential, mitochondrial complex I activity and mitochondrial encoded genes (i.e. NADH dehydrogenase 1, 3, 6 and ATP synthase 6) are modulated by corticosterone in a dose and time-dependent manner (Du et al. 2009; Hunter et al. 2016). In parallel, a reduction of the activity of specific mitochondrial electron transport chain complexes together with an increased mitochondrial Reactive Oxygen Species (ROS) production has been shown under chronic glucocorticoid treatment (Manoli et al. 2007), which could impact the oxidative balance (Costantini 2011). Altogether, these physiological studies

72 thus demonstrated (i) a time adjustments of energetic resources in response to stress and (ii) a
73 direct linkage between GC secretion in response to stressor and mitochondrial physiology.

74 These observations led to the emergent concept of "mitochondrial allostatic load" that is the
75 mitochondrial analog of allostatic load in the broader context of stress biology (McEwen and
76 Wingfield 2003). The mitochondrial allostatic load can be defined as the "deleterious structural
77 and functional changes that mitochondria undergo" in response to elevated glucocorticoid
78 secretion under a chronic stress situation (Picard et al. 2014, 2018). The mitochondria are the
79 major ATP cell generators (Lehninger et al. 1993) sustaining physiological processes
80 underlying both maintenance and physiological responses to environmental variations.
81 Mitochondrial energy transduction system also continually produces ROS which can be
82 involved in cell signaling and/or physiopathology (Starkov, 2008). Unfortunately, at that time,
83 no direct assessments of mitochondrial functionality parameters like ATP and ROS under
84 chronic GCs production were available. Yet such data are crucial to understand functional
85 consequences of previously described responses to GC secretion, such as alteration of gene
86 expression and/or epigenetic modifications (Hunter 2016), increased oxidized mtDNA and
87 mitochondrial fission (Picard et al. 2014). A better knowledge of the temporal dynamics of
88 mitochondrial responses to GC secretion will undoubtedly have biomedical applications but
89 will also provide new visions in evolutionary biology (Eisner et al. 2018).

90 The objective of this study was to explore the time-dependent metabolic responses at
91 the whole-body and mitochondrial levels in lizards (*Zootoca vivipara*) exposed to 3 days, 11
92 days and 21 days of corticosterone treatment. This protocol provides the temporal dynamic of
93 the mitochondrial responses to GC secretion and answers the following three questions. First
94 question: do short-term *versus* long-term elevations in GCs production induce similar
95 physiological responses in ectotherms than in endotherms? Indeed, the commonly accepted
96 conclusions on time effects on GCs impacts are strongly biased toward endotherms (mammals

and birds), neglecting the vast majority of ectothermic metazoans. Recent experimental approaches suggest different mitochondrial responses under stress in some ectotherms (e.g., Cote et al. 2010; Voituron et al. 2017). Comparative analyses demonstrate that evolution shapes GCs variations which leads to a different impact between ectotherms and endotherms (Jessop et al. 2013; Vitousek et al. 2019). Second question: are ATP and ROS productions equivalently impacted by GCs? Third question: given that the liver and muscle contribute about 50% of body O_2 consumption at rest and more during activity (Rolfe and Brown, 1997), does whole-organism metabolism correctly reflect energetic adjustments at a cellular level of organization?

Materials and methods

Capture and rearing condition

The common lizard (*Zootoca vivipara*) is a small lacertid species (adult's snout-vent length SVL ranging from 50–70 mm) widely distributed across Eurasia. In spring 2016, 49 sub-adult males (1-year-old) were captured by hand in outdoor enclosures (10 × 10 m) at CEREEP (Centre de Recherche en Ecologie Expérimentale et Prédictive; Saint-Pierre-lès-Nemours, France, 48°17´N, 2°41´E) field station from May 16th to May 25th. Animals were measured for body size (SVL, ± 0.5 mm) and body mass (± 1 mg). All animals were maintained in individual terraria (25 × 15 × 16 cm) with a shelter, peat soil as substrate and opportunities for optimal thermoregulation. We used incandescent light bulbs (25 W) for 8 hours per day from 09:00 to 17:00 local time to ensure a thermal gradient ranging from 17-23°C to 35-38°C. We provided lizards with water *ad libitum* and, every other day, with 300 ± 20 mg of food (*Acheta domestica*).

Experimental design and whole-organism assays

The study was performed between June 12th and July 12th 2016. At the start of the experiment, animals were distributed in six groups corresponding to two experimental treatments

122 (corticosterone enhancement [CORT] and placebos [CONT]) and three treatment exposure
123 groups (3 days [3D], 11 days [11D] and 21 days [21D] of exposure to experimental treatments
124 until the functional analyses of mitochondria). Similar sample sizes (N=8) were used in each
125 group except in the CORT-21D group (N=9). We repeatedly measured the body mass and
126 whole-organism metabolic expenditure 3 days before the start of the experiments, and the day
127 before the cellular and mitochondrial measurements meaning days 2, 10 and 20 (in 3D, 11D
128 and 21D groups respectively) after the start of the experiment. Before each whole-organism
129 assay, the animals were left without food for 3 days to reach the post-absorptive state. After the
130 final assay, the animals were fed and treated with corticosterone according to their treatment
131 group. Then, the animals were euthanized to perform functional analyses of mitochondria (see
132 below and Figure 1).

133 Whole-organism metabolic expenditure at night was quantified with closed respirometry
134 techniques as previously described (Foucart et al., 2014). We measured oxygen consumption
135 and carbon production overnight (approximately 20:00–08:00h) in a dark climatic chamber
136 (AQUALYTIC® TC 135S, Dortmund, Germany). Trials were carried out at 25±1°C, which
137 correspond to body temperature at which functional analyses of mitochondria were performed
138 *in vitro* (see below). The lizards were placed individually into glass jars (ca. 1,000 ml) within
139 the chamber and allowed to acclimatize for 1h. A baseline air sample (two 140 ml syringes)
140 was collected at the onset of the trial, and the glass vial was then carefully sealed. The trial
141 duration was set to achieve adequate oxygen suppression based on previous studies and
142 preliminary trials (mean=11.8 h, range=11.2-12.1h). A final sample of air was collected with
143 two 140 ml syringes connected to a stopcock. Oxygen and CO_2 concentrations (% of total
144 volume) of the air samples were determined using fuel-cell O_2 and infrared CO_2 sensors
145 (FOXBOX, Sable Systems, Las Vegas, NV, USA) at room temperature with a constant flow (60
146 $ml.min^{-1}$) after water absorption through a column of Drierite. Oxygen consumption (VO_2, in

ml min^{-1}) and CO_2 production (VCO_2) were calculated as: (final % – initial %) × exact chamber volume (ml)/trial duration (min). Body mass was recorded to the nearest mg before each trial. Respiratory quotient (RQ) was calculated like VCO_2/VO_2 and ranged from 0.60 to 0.82 [mean = 0.72, 95% CI= 0.71-0.73]. We found no treatment effect on RQ (ANOVA, $F_{1,47}$=0.65, P = 0.42), but parallel, temporal changes in RQ for both control and treated lizards ($F_{3,96}$=36.59, P < 0.0001). Since the theoretical RQ value for lipid substrates is 0.71, we therefore assumed that most lizards used stored lipids as the main energy source and used energy equivalents for lipids (19.8 J.mL^{-1}) to convert VO_2 into standard metabolic rates (SMR) values (in J.min^{-1}). These metabolic measurements proved to be extremely reliable and repeatable compared to our earlier studies (Foucart et al., 2014).

Hormonal manipulation and plasma corticosterone assays

Circulating levels of corticosterone were enhanced using a non-invasive method designed by Meylan et *al.* (2003). We diluted corticosterone (Sigma-Aldrich, France, C2505-500mg 92%, $C_{21}H_{30}O_4$) in commercial sesame oil according to 3µg of corticosterone per 1µL of sesame oil. Each evening between 20:00 h and 21:00 local time (when lizards are mostly inactive), 4.5 µL of corticosterone mixture (CORT) or pure sesame oil (CONT, a placebo) were topically applied on the backs of the lizards. To check effects on plasma levels of corticosterone, blood was sampled from the infraorbital sinus of the lizards 7 days before the start of the experiment and at the end of the treatment exposure using 2–3 20 µL microhematocrit tubes. In order to standardize the measurements, all samples were collected between 15:00 h and 16:00 local time within 3 min of removal of an animal from its home cage to avoid the handling-induced increase in plasma corticosterone levels (Dauphin-Villemant, 1987). Plasma was obtained by centrifugation at c.a. 5,000 *g* for 5 minutes of the blood samples and was stored at -40°C for subsequent measurements of plasma levels of corticosterone. Corticosterone level was measured with a competitive enzyme-immunoassay method using corticosterone EIA (IDS

172 Corticosterone EIA kit, ref AC-14F1, IDS EURL Paris, France) after 1:10 dilution of all
173 samples following previously published guidelines (Mugabo, 2017).

174 ***Respiratory capacities of muscular permeabilized fibres***

175 At the end of the experiment, animals were euthanized by decapitation. Skeletal muscles were
176 rapidly and entirely dissected, weighed and then placed in an ice-cold isolation buffer (BIOPS
177 containing 2.77 mM Ca-EGTA, 7.23 mM, 20 mM imidazole, 20 mM taurine, 50 mM K-MES,
178 0.5 mM DTT, 6.56 mM $MgCl_2$, 5.77 mM ATP, 15 mM phosphocreatine, pH 7.2). Skeletal
179 muscle fibres were permeabilized in BIOPS solution supplemented with saponin (50 µg ml^{-1})
180 according to a standard protocol (Pesta and Gnaiger, 2012). Permeabilized fibres were weighed
181 and their respiration were monitored with a high-resolution respirometer (Oxygraph-2k,
182 Oroboros Instruments; Austria) in a hyper-oxygenated respiratory buffer maintained at 25 °C
183 (110 mM sucrose, 0.5 mM EGTA, 3 mM $MgCl_2$, 60 mM K-lactobionate, 20 mM taurine, 10
184 mM KH_2PO_4, 1 g l^{-1} fatty acid-free bovine serum albumin, 20 mM Hepes, pH 7.1). A mixture
185 of respiratory substrates (5 mM pyruvate, 2.5 mM malate and 5 mM succinate) was added to
186 obtain the basal respiration (state 2). Cellular ATP synthesis was initiated by the addition of 1
187 mM ADP. The maximal fully uncoupled respiration (state 3_{unc}) was initiated by addition of 2
188 µM carbonyl cyanide p-tri-fluoro-methoxy-phenyl-hydrazone (FCCP), in presence of
189 oligomycin (2 µg ml^{-1}), an inhibitor of ATP synthase.

190 ***Extraction of liver and functional analyses of mitochondria***

191 After weighing the liver, the mitochondria were isolated in an ice-cold isolation buffer (250
192 mM sucrose, 1 mM EGTA, 20 mM Tris-HCl, pH 7.4 at 4°C) as previously described (Voituron
193 et al., 2017). Briefly, the isolation procedure involved Potter-Elvehjem homogenization (three
194 passages) and differential centrifugations (all steps at 4°C), with the liver mitochondria being
195 pelleted at 9,000×*g* (10 min). The protein concentration of mitochondrial suspension was
196 spectrophotometrically determined at 540 nm by a Biuret method with bovine serum albumin

as a standard. Because lizard mitochondrial preparations contained a dark pigment that absorbed at 540 nm, the absorbance of the same volume of mitochondria in a solution containing 0.06% Na deoxycholate, 0.6% K-Na-tartrate and 3% NaOH was subtracted.

Rates of oxygen consumption and ATP synthesis were measured in a closed glass cell fitted with a Clark oxygen electrode (Rank Brothers Ltd, UK) at 25°C in a respiratory buffer containing 120 mM KCl, 5 mM KH_2PO_4, 1 mM EGTA, 2 mM $MgCl_2$, 0.3 % fatty acid-free bovine serum albumin, 1.6 U/ml hexokinase, 20 mM glucose, 3 mM Hepes (pH 7.4). Liver mitochondria (0.5-1.5 mg/mL) were energized with a mixture of substrates (5 mM pyruvate, 2.5 mM malate and 5 mM succinate). Mitochondrial ATP synthesis was initiated by the addition of 500 µM ADP. After recording the phosphorylating respiration rate for 3 min, four 100 µL samples were withdrawn from the suspension every 1 min and were quenched in 100 µL ice-cold perchloric acid solution consisting of 10% $HClO_4$ and 25 mM EDTA. After centrifugation (15,000×*g*, 5 min) and neutralization of the resulting supernatant with a KOH solution (2 M KOH, 0.3 M MOPS), ATP production was determined from the slope of the linear accumulation of glucose-6-phosphate content of samples (Voituron et al., 2017). To make sure that the rates we measured were specific of the mitochondrial ATP synthase activity and not associated with contaminated ATPase activity such as adenylate kinase, we determined oxygen consumption and ATP synthesis rates in the presence of oligomycin (2 µg/mL). These values were taken into account to calculate the rate of mitochondrial ATP synthesis that is associated with mitochondrial ATP synthase activity and oxygen consumption.

Mitochondrial reactive oxygen species production

The rate of H_2O_2 released by isolated liver mitochondria was measured at 25°C in a respiratory buffer supplemented with 5 U/mL horseradish peroxidase and 1 µM Amplex red fluorescent dye using a fluorescence spectrophotometer (SFM-25, Kontron Instrument) at excitation and emission wavelengths of 560 nm and 584 nm, respectively. The fluorescent signal was

222 calibrated using a standard curve obtained after successive addition of H_2O_2 (up to 35 pmoles).
223 Amounts of H_2O_2 release were corrected from background rate of product formation in the
224 absence of exogenous substrate as described previously (Voituron et al., 2017). Free radical
225 electron leak (ROS/O ratio) was calculated as the fraction (%) of basal non-phosphorylating
226 oxygen consumption that is reduced into H_2O_2 at the respiratory chain instead of H_2O at the
227 cytochrome-c oxidase. Similarly, the oxidative cost of mitochondrial ATP synthesis was
228 calculated from the ratio of H_2O_2 generation under phosphorylating state divided by the
229 corresponding rate of ATP synthesis (ROS/ATP ratio).

230 **Statistical analyses**

231 All statistical analyses were performed with linear models in R 3.3.2 (R Development Core
232 Team, 2015). We first checked the effects of treatment groups on change in plasma
233 corticosterone levels from before the end of the experiment with a linear model fitted with the
234 *lm* package (Venables and Ripley, 2002). We included initial plasma corticosterone level and
235 body mass as covariates in this model. Next, repeated measurements (body mass and SMR)
236 were analyzed with mixed-effects linear models in the *lme* package. Dependence among
237 repeated measurements were accounted using random intercept model where the intercept of
238 the model is allowed to vary randomly among individuals. A compound symmetry covariance
239 structure that includes within-subject correlated errors was used and the random term was
240 always kept in the models. This model assumes that individuals react in the same way to
241 treatments and provides information about intra-class correlations and therefore consistency of
242 inter-individual differences. In addition, all models included fixed effects of experimental
243 treatments, treatment exposure groups (categorical variable) and their interactions. Since SMR
244 increases exponentially with body mass, we log transformed SMR prior to the analyses and
245 included log-transformed body mass as a covariate in the analyses. The normality and
246 homogeneity of variance of residuals was systematically checked in the full models and was

found to be satisfactory. In a third set of analyses, we compared final measurements of liver mass and mitochondria functioning across treatment groups with a linear model including fixed effects of experimental treatments, treatment exposure groups and their interactions. In all models, the significance of fixed effects was tested with type III F statistics using the *Anova* procedure in the *car* package. We removed non-significant variables (α=0.05) one by one using a backward elimination procedure. Whenever significant differences were found among treatment groups, we used Tukey's procedure to conduct post hoc tests (pairwise comparisons between the experimental groups) with the *lsmeans* package (Lenth, 2016). Results are presented as mean ± standard error unless otherwise stated.

Results

Corticosterone supplementation increases body and liver masses

Before the experiment, animals had similar SVL, body mass and body condition, SMR and initial plasma corticosterone levels among treatment groups (ANOVA, all $P > 0.66$). Analysis of intra-individual change in plasma corticosterone levels confirmed that treated groups exhibited higher concentration over the entire experiment (treatment: $F_{2,44}$=71.6, $P < 0.0001$; exposure group: $F_{2,44}$=6.49, $P = 0.003$). On average, plasma corticosterone levels were 154.8 $ng.mL^{-1}$ (± 18.3) higher in treated than in control lizards, similar to previous effects reported with the same protocol (Voituron et al. 2017). In addition, treated lizards exhibited an increase of body mass over time (+2% at 3D, +5% at 11D and +17% at 21D), whereas the body mass of control lizards did not change significantly over time (treatment × exposure group: $F_{3,94}$=18.13, $P < 0.0001$) (see Table 1). Total liver mass (treatment × exposure group: $F_{2,43}$=8.24, $P = 0.0009$) and relative liver mass (g of liver per 100 g body mass; liver mass controlled for variation in body mass; treatment × exposure group: $F_{2,42}$=8.33, $P = 0.0009$) differed also between

271 treatments after 11 days of exposure only. There was a significant increase of liver mass at D11
272 and D21 in treated lizards relative to controls (Table 1).

273 **Corticosterone supplementation and whole-organism oxygen consumption**

274 Overall, SMR remained relatively similar between treatments apart for a slight, close to
275 significant decrease in SMR from treated lizards relative to controls at D21 (Table 1; treatment
276 × exposure group: $F_{3,92}$=2.69, P = 0.05; Student's *t* test at D21: P = 0.07). However, when
277 controlling for the positive relationship between individual body mass and individual SMR
278 (log-log slope=0.67 ± 0.13; $F_{1,90}$=25.78, P < 0.0001), the best fit model indicated that mass-
279 corrected SMR differences over time between treatments ranged from a small positive
280 difference for CORT at D3, followed by a return to normal at D11, and a significant decrease
281 in mass-corrected SMR from treated lizards at D21 (treatment × exposure group: $F_{3,90}$=5.01,
282 P=0.003). These results can be interpreted as evidence that corticosterone treated lizards
283 maintained relatively similar whole-organism SMR despite their increase in body mass during
284 the 21-day long exposure period, thus had lower mass-corrected SMR through time.

285 **Corticosterone supplementation and liver mitochondrial functions**

286 The treatment affected mitochondrial activities with contrasted effects between the rates of ATP
287 synthesis and oxygen consumption over the course of the study (Table 1 and Figure 2, see Table
288 S1 for statistical details). The rate of ATP synthesis was significantly lower in the corticosterone
289 treatment irrespective of treatment exposure. In contrast, both basal and phosphorylating rates
290 of oxygen consumption did not change after 3 days of treatment, then were significantly
291 decreased in 11-day treated lizards compared with control animals, and eventually returned to
292 same levels than in controls at day 21 (Table 1). Consequently, mean values of the mitochondrial
293 coupling efficiency (ATP/O ratio) were significantly decreased after 3 days of corticosterone
294 treatment, but were not significantly different from control values after 11 days and 21 days of
295 treatment (treatment × exposure group: $F_{2,41}$=4.14, P = 0.02, see Figure 2).

The rates of mitochondrial reactive oxygen species production under both basal non-phosphorylating and active phosphorylating states were not significantly altered after 3 days of glucocorticoid treatment but exhibited between 40% to 50% decrease in treated lizards relative to controls after 11 and 21 days (Table 1, see Table S1 for statistical details). Overall, the electron leak defined by the ROS/O ratio was not significantly changed by the glucocorticoid treatment neither in basal non-phosphorylating state (treatment × exposure group: $F_{2,41}$=2.09, P = 0.14; treatment: $F_{1,43}$=0.13, P = 0.82; exposure group: $F_{2,44}$=10.21, P = 0.0002) nor in active phosphorylating state (treatment × exposure group: $F_{2,41}$=1.81, P = 0.18; treatment: $F_{1,43}$=0.89, P = 0.35; exposure group: $F_{2,44}$=2.26, P = 0.12). In contrast, the oxidative cost of ATP synthesis (ROS/ATP ratio) was marginally affected by hormonal treatment, being higher in the 3-day treated group than in the control group, but returning to the level of control groups after 11 days and 21 days of treatment (treatment × exposure group: $F_{2,41}$=3.02, P = 0.06; see Figure 3).

Corticosterone supplementation and muscle mitochondria functioning

Whatever the state of activation (basal non-phosphorylating, phosphorylating and maximal), cellular oxygen consumption of lizard muscle was not different between control and treated individuals neither at 3 days, 11 days nor at 21 days of treatment (Table 1 and Table S1).

Discussion

This study aimed at unraveling the time-dependent mechanisms linking corticosterone and metabolism at different levels of organization (whole-organism, cellular and mitochondrial) in an ectothermic organism. The data presented here provide first clear evidence of GC-dependent regulation of the liver mitochondrial functionality in a time-dependent manner leading to a "functional resilience" after 21 days of chronic corticosterone increase. Indeed, short-term GC supplementation induced a significant decrease of mitochondrial ATP synthesis without change of oxygen consumption and H_2O_2 release, thus causing a lower efficiency (ATP/O) and a higher

321 oxidative cost of an ATP molecule production (ROS/ATP). In contrast, longer-term GC
322 supplementation induced a significant decrease of mitochondrial H_2O_2 release with
323 mitochondrial oxidative phosphorylation characteristics to returning to the same level than
324 controls. In an important synthesis, Mc Ewen and Wingfiels (2003) defined the allostatic state
325 as the "*altered and sustained activity levels of the primary mediators, e.g., glucocorticosteroids,*
326 *that integrate physiology and associated behaviors in response to changing environments and*
327 *challenges such as social interactions, weather, disease, predators, pollution, etc*". The present
328 data show that liver mitochondria decrease first their efficiency and then their fluxes (both in
329 terms of O_2 and ATP) but restore their functional capacity in response to the energetic
330 dysfunction imposed by the endocrine variations. In addition, the data also suggest a tissue
331 dependent response, with corticosterone treatment affecting functioning of mitochondria in the
332 liver but not that of skeletal muscles. Interestingly, changes in metabolism of mitochondria *in*
333 *vitro* were not reflected by variation in the whole-organism metabolism *in vivo*.

334 The present data expand results of a previous study on this species (Voituron et al. 2017)
335 providing the time dynamics of functional regulation of the mitochondrial oxygen consumption,
336 ATP and H_2O_2 productions under GC secretion. In response to the glucocorticoid
337 supplementation, the liver mitochondria first lowered its ATP synthesis rate without changing
338 its oxygen consumption (see Figure 2). Even if mechanisms underpinning this lower efficiency,
339 the cellular ATP/AMP ratio being modified, a cascade of genes upregulation required for
340 mitochondrial respiratory chain expression and function is triggered (Teperino et al. 2010;
341 Mouchiroud et al. 2014). At 11 days of treatment, the mitochondrial pattern is characterized by
342 low values of all fluxes reflecting a diminished activity of the respiratory chain. Interestingly,
343 this mitochondrial hypometabolism restored both the efficiency (ATP/O) and oxidative cost of
344 an ATP molecule production (ROS/ATP). Altogether, these elements are in line with scenarios
345 of downregulation of the respiratory chain subunits (Pandya et al., 2004) and of the activity of

346 substrate oxidation reported after glucorticoids treatment in rodents (Roussel et al., 2004; 347 Arvier et al., 2007). The nearly total recovering of both oxygen and ATP after 21 days of 348 treatment associated with lower ROS release might be ascribed to *de novo* mitogenesis 349 (Jornayvaz and Shulman 2010). Indeed, glucocorticoids can induce higher expression of key 350 nuclear genes that are required to produce new mitochondria (Psarra and Sekeris 2011). Such a 351 functional resilience in terms of ATP production associated with lower H_2O_2 production 352 corroborates previous results on male common lizards that showed lower superoxide dismutase 353 activity in corticosterone-treated individuals after 21 days (Cote et al. 2010). These results are 354 however not congruent with data on endotherms in which chronically elevated GC levels 355 accelerate aging and reduce lifespan (Schoenle et al. 2018), thus imposing fitness costs 356 potentially through oxidative balance (Costantini 2011).

357 All these mitochondrial adjustments occurred without modification of whole-organism 358 metabolism (present study; Voituron et al. 2017). Even if only two tissues were tested in the 359 study, the data thus strongly suggest that whole-organism oxygen consumption cannot be used 360 as an accurate proxy for neither ATP production nor ROS release by tissue-specific 361 mitochondria (Salin et al. 2015). However, the GC effect on whole-organism metabolism, an 362 important parameter of the total energy budget, still remains an open question since it has been 363 demonstrated that chronic increase of corticosterone slightly increases metabolic rates at rest in 364 pregnant female common lizards (Meylan et al. 2010) when other lizard species reduce their 365 total oxygen consumption rate when exposed to an increase in corticosterone (Miles et al. 2007; 366 Durant et al. 2008). Nevertheless, the functional mitochondrial resilience observed *in vivo* 367 might constitute a proximal explanation of the increase in survival of male common lizards with 368 corticosterone enhancement (Meylan and Clobert 2005; Cote et al. 2006).

369 Even if oxygen consumption between tissues has been assessed at different levels of 370 organization, the data suggests that muscles and liver showed differential response patterns.

This statement would be wrong only if mitochondrial content in muscles strongly increase during acute and mild-time stress that has never been reported and not congruent with mitogenesis dynamic (Jornayvaz and Shulman 2010). The data available on mammals are puzzling with no muscular effect in rodents under dexamethasone (Dumas et al. 2003, Roussel et al. 2004) or muscle wasting mediated, in part, by GR-dependent transactivation of genes that drive myocyte atrophy (Patel et al. 2014). In addition, the muscular impact of GC is dose-dependent with moderate or transient exposure to GCs enhancing muscle performance (Caruso et al. 2014). Even if muscles of common lizards do not exhibit a mitochondrial response, muscles could be involved as amino-acids source for liver neoglucogenesis under corticosterone.

Conclusions and perspectives

This study demonstrates that liver mitochondrial energetics of ectotherms is directly influenced in a time-dependent manner by exposure to higher plasma concentrations of circulating GCs. After chronic exposure to GCs, the liver mitochondria reached a functional resilience with a complex interplay between O_2 consumption, ATP production and H_2O_2 release. The coupling between these three mitochondrial processes is thus plastic and differentially regulated leading to a critical period when stress is acute (low ATP production with high H_2O_2 release), an intermediate period when efficiency returns to the initial levels but with low respiratory chain activity, and finally a complete “recovery” to the initial fluxes and ratios. This time-dependent relationship between GC and mitochondria in ectotherms needs to be taken into account to better understand mechanisms that ensure and drive the flow of energy during physiopathological responses (e.g., Rohleder 2012) but also towards adaptive processes.
