Abstract: In the past decades, shellfish culture has developed in a significant way around the world. However, culture areas are often subject to recurring anthropic pollution. The recrudescence of industrial wastes is a source of heavy metals and results in pollutant transfer towards the aquatic environment in estuarine areas. Because of their mode of life, bivalves, including mussels and oysters, are suggested as ideal indicator organisms. The development of techniques allowing the analysis of the effects of pollutants on bivalve biology may lead to the monitoring of pollutant transfer in estuarine areas. In this context, the effects of cadmium and mercury on defence mechanisms were analysed in Pacific oysters, *Crassostrea gigas*. Pollutant effects were tested in vitro on oyster haemocytes. Cell viability and enzymatic activities (esterase, peroxidase, aminopeptidase, phagocytosis activities) were monitored by flow cytometry. Enzymatic phenoloxidase-like activity was also evaluated by spectrophotometry. High pollutant concentrations were used in order to detect the acute effect and to approach real pollutant concentrations existing in animal tissues. Cadmium induced no effect on oyster haemocytes under the tested conditions. On the contrary, mercury caused a significant haemocyte mortality after a 24 h in vitro incubation. Aminopeptidase positive cell percentage was enhanced by the pollutant, and phenoloxidase-like activity was inhibited. These in vitro results show that mercury may be expected to have an impact on bivalve immune functions in contaminated areas.

I. INTRODUCTION

For several decades, shellfish culture has developed in a significant way around the world and particularly in France. The most economically important bivalve species is the Pacific oyster, *Crassostrea gigas*. This species is frequently reared in disturbed ecosystems subject to pollutants which affect the environmental quality of coastal waters.

Among environmental pollutants, heavy metals may have major ecological consequences. Some of the pollutants introduced in land and aquatic ecosystems may possess an important toxic potential (1). Metals are not degradable and may thus persist for long periods in ecosystems. Moreover, physical, chemical and biological processes have a greater tendency to concentrate than to dilute heavy metals (2). In this way, aquatic animals including marine bivalves are likely to be exposed to elevated concentrations of pollutants. Oysters and other bivalve molluscs have been postulated as ideal indicator organisms for the assessment of environmental pollution (3, 4). They are already used in different programs monitoring pollution in estuarine ecosystems. Through their ubiquitous, benthic and sedentary mode of life, they are exposed to environmental modifications (temperature, salinity, pollutants, etc.) with no escaping possibility (5, 6). Their suspensivore mode of nutrition allows them to concentrate xenobiotics within their tissues by filtration of large volumes of seawater (7). Pollutant bioconcentration varies according to each pollutant and animal species but it may reach considerable levels. The reactions of animals faced with pollutants depend on the particular type of pollutant, nevertheless bioaccumulation constitutes a common response. Such a bioaccumulation may be the consequence either of a direct contamination by water or an indirect contamination by food (8).

Although numerous studies have been made concerning the accumulation and toxic effects of heavy metals in bivalve molluscs, little effort has been directed at determining their toxic effects at a cellular level (9). Molluscs possess an open circulatory system which is continually exposed to the fluctuations of environmental factors including contaminants (10). The cellular defence system of bivalves comprises haemocytes which have various activities including phagocytosis, intracellular degradation of pathogens by means of hydrolytic enzymes, production of reactive oxygen metabolites and phenoloxidase activity (11, 12, 13). The effects of environmental contaminants may correspond to a direct toxic action on tissues or cells or to more subtle alterations in homeostatic mechanisms including the immune system (14, 15).

Most studies on immunotoxicity consist in the collection of animals located on polluted sites and the determination of immune activity variations during a long period of time (16,

17, 18, 19, 20, 21). However, in the present work, *in vitro* effects of different compounds in direct contact with *Crassostrea gigas* haemocytes were investigated. This approach may confirm results obtained from previous *in vivo* or *in situ* experiments. Moreover, this approach is suitable for developing immunotoxicity models in order to determine the mode of action of a particular pollutant. The actual aim of the present study was to work in acute toxicity conditions in order to obtain a rapid effect of heavy metals on immune cellular and plasmatic activities. Two heavy metals were selected (mercury and cadmium) and tested at different concentrations. Two forms of mercury were used : mercury chloride, which is the form rejected by industries, and methylmercury, potentially more toxic. The presence of these pollutants was reported in different shellfish culture areas at episodic high concentrations (22). Effects on haemocytes were studied using flow cytometry. Flow cytometry allows rapid analyses of the morphological and functional characteristics of free cell suspensions (23). Resulting data were based on autofluorescence light scattering parameters related to cell size and complexity (granularity). Cellular functions were also investigated using fluorescent markers : cell viability, presence of hydrolytic enzymes, and phagocytic activity. Phenoloxidase-like activity was also studied in the plasma fraction of haemolymph by spectrophotometry.

II. MATERIAL AND METHODS

Animals

Pacific oysters, *Crassostrea gigas*, 8-10 cm in shell length were purchased from a shellfish farm located in Marenne-Oleron Bay (La Tremblade, Charente-Maritime, France) from February 2001 to April 2002. Two year-old animals originated from the same resource and were immediately processed after their arrival in the laboratory.

Circulating haemocyte collection

After opening oyster shell by cutting off the adductor muscle, haemolymph was withdrawn from the pericardial cavity using a 1-mL syringe equipped with a needle (0,9525 mm). For each oyster, 0.5-1 mL of haemolymph was collected. Haemolymph samples were conserved on ice to prevent haemocyte aggregation (24). Haemolymph samples were pooled to reduce interindividual variation and to provide enough haemocytes in order to fulfil requirements of pollutant exposure assays.

Xenobiotics and exposure protocols

Experiments consisted of an *in vitro* contact between haemocytes and selected pollutants. Analysis was carried out after different times of contact with the pollutant (4 or 24 h). Incubations were realised in the dark at 20°C. Three pollutants were tested : cadmium chloride (CdCl₂ anhydre, Sigma), mercury chloride (Mercure (II) chloride (HgCl₂), Rhône Poulenc), and methylmercury (CH₃HgCl, Sigma).

Cadmium chloride

Eight concentrations were tested: 3.10⁻¹¹, 3.10⁻¹⁰, 3.10⁻⁹, 3.10⁻⁸, 3.10⁻⁷, 3.10⁻⁶, 3.10⁻⁵ and 3.10⁻⁴ M. Solutions were prepared in distilled water. Pollutant was added at 10 µL per milliliter of haemolymph in order to limit osmolarity modification.

Twenty oysters were punctured and haemolymph samples were filtered on a 70 µm mesh to eliminate debris. The haemolymph was then centrifuged (260 g, 15 min, 10°C) and cellular pellets were resuspended in 5 mL of filtered seawater (FSW) added with antibiotics (kanamycin, erythromycin and oxolinic acid, 0.1 mg.mL⁻¹). Cellular concentrations were adjusted to 10⁶ cells.mL⁻¹.

Haemocytes were incubated at 20°C for 4 and 24 h. Mortality of haemocytes was evaluated. These experiments were carried out twice.

Mercury

Methylmercury

Eight concentrations were tested: $2 \cdot 10^{-11}$, $2 \cdot 10^{-10}$, $4 \cdot 10^{-10}$, $2 \cdot 10^{-9}$, $2 \cdot 10^{-8}$, $2 \cdot 10^{-7}$, $4 \cdot 10^{-7}$ and $2 \cdot 10^{-6}$ M. Initial solution was prepared in 14 N nitric acid (HNO_3) and further dilutions were prepared in distilled water. Pollutant was added at $10 \mu\text{L} \cdot \text{mL}^{-1}$ haemolymph.

Exposure protocol was similar to cadmium chloride protocol. Haemocytes were incubated at 20°C for 4 and 24 h. Haemocyte mortality was evaluated. Experiments were carried out twice.

Mercury chloride

Two series of experiments were carried out using HgCl_2 :

1- 4 concentrations were tested: $2 \cdot 10^{-7}$, $2 \cdot 10^{-6}$, $2 \cdot 10^{-5}$ and $2 \cdot 10^{-4}$ M. Initial solution was prepared in 0.3 N nitric acid (HNO_3) and further dilutions were prepared in distilled water. The pollutant was added at $1 \mu\text{L} \cdot \text{mL}^{-1}$ haemolymph. Exposure protocol was similar to cadmium chloride protocol.

Haemocytes were submitted at 4 treatments : (i) centrifugation with resuspending in FSW; (ii) centrifugation with resuspending in FSW supplied with antibiotics (flumequin $30 \text{ mg} \cdot \text{mL}^{-1}$, penicillin $0.75 \text{ mg} \cdot \text{mL}^{-1}$, streptomycin $1.5 \text{ mg} \cdot \text{mL}^{-1}$, and kanamycin, oxolinic acid, and erythromycin $0.1 \text{ mg} \cdot \text{mL}^{-1}$) ; (iii) no centrifugation and addition of the same antibiotics ; (iiii) no centrifugation and no antibiotics.

Haemocytes were incubated at 20°C for 4 and 24 h. Haemocyte mortality was evaluated. Experiments were carried out three times.

2- 3 concentrations were tested: $2 \cdot 10^{-6}$, $2 \cdot 10^{-5}$ and $2 \cdot 10^{-4}$ M. All solutions were prepared in 0.3 N nitric acid (HNO_3) to preserve their activity (25). Twenty oysters were punctured and haemolymph samples were pooled. The pollutant was added at $10 \mu\text{L} \cdot \text{mL}^{-1}$ haemolymph. Haemocytes were incubated 4 and 24 h at 20°C . Haemocyte parameters were evaluated (enzymatic activities, phagocytosis, mortality). Experiments were repeated three times.

Cell analysis by flow cytometry

Haemocyte analysis using flow cytometry (EPICS XL 4, Beckman Coulter) was previously described (26). For each haemocyte sample, 10 000 events were counted. Results were expressed as cell cytograms indicating the size (FSC value), the complexity (SSC value) and the fluorescence channel(s) corresponding to the marker used. Recorded fluorescence

depended on the monitored parameters : enzymes and phagocytosis were measured using FL1 and mortality using FL3.

Mortality was quantified using 200 μL of haemolymph. Haemocytes were incubated in the dark for 30 min at 4 °C with 10 μL of propidium iodide (PI, 1.0 $\text{mg}\cdot\text{mL}^{-1}$, Interchim).

Esterase, aminopeptidase and peroxidase activities were evaluated with commercial kits (Cell Probe TM Reagents, Beckman Coulter). Each analysis required 200 μL of haemolymph and 20 μL of the corresponding kit (FDA•Esterase, A•Aminopeptidase M and DFCH, PMA•Oxidative Burst). Haemocytes were incubated in the dark at ambient temperature for 15 min for esterases and peroxidases and for 30 min for aminopeptidases. PMA-peroxidase activity was specifically inhibited using sodium azide (NaN_3 , Sigma) at different concentrations : $3\cdot 10^{-7}$, $3\cdot 10^{-6}$, $3\cdot 10^{-5}$, $3\cdot 10^{-4}$, 10^{-3} , 10^{-2} , $2\cdot 10^{-2}$, $3\cdot 10^{-2}$, $6\cdot 10^{-2}$ M. Aminopeptidase activity was inhibited using bestatin (Sigma) at two concentrations : $5\cdot 10^{-4}$ and $5\cdot 10^{-3}$ M.

Phagocytosis was measured by ingestion of fluorescent beads. Five hundred μL of haemolymph were incubated for 1 h in the dark at ambient temperature with 10 μL of a 1/10 dilution of Fluorospheres[®] carboxylate-modified microspheres (diameter 1 μm , Interchim). Phagocytosis was controlled using epifluorescence microscopy (27) (data not shown).

Phenoloxidase-like (PO-like) activity detection

Haemolymph samples were centrifuged (260 g, 10 min, 4°C). The acellular fraction (supernatant) was frozen at -20°C for further analysis. Detection of PO-like activity in acellular fraction samples was carried out by measurement of L-Dopa transformation in dopachromes. Transformation was monitored by spectrophotometry at 490 nm. Samples were distributed in 96 well microplates. Purified trypsin TPCK (N-Tosyl-L-phenylalanine chloromethyl ketone, $1\text{g}\cdot\text{L}^{-1}$, Sigma) was tested as an activator of PO activity. Phenylthiourea PTU (1-Phenyl-3-(2-Thiazolyl)-2-Thiourea, 10 mM, Sigma), a specific inhibitor of PO activity, was also tested. Sixty μL of cacodylate buffer (CAC), 20 μL of a PO activity modulator, 20 μL of L-Dopa (L-3,4-dihydroxyphénylalanine, 3 $\text{mg}\cdot\text{mL}^{-1}$, Sigma) and 20 μL of sample were added in each well. PO-like activity detection in presence of mercury was carried out. Mercury (HgCl_2) was used at $2\cdot 10^{-6}$ and $2\cdot 10^{-5}$ M and 1 μL was added in presence of TPCK.

Statistical analysis

For each pollutant, cellular parameters were analysed three times after 4 and 24 h incubations. Results were analysed using a non-parametric Kruskal-Wallis test for independent samples. H_0 was rejected when $p \leq 0.05$. In the case of the reject of H_0 , an *a posteriori* Student-Newman-Keuls (SNK) test was used.

III. RESULTS

Pollutant effects on haemocyte mortality

Incubations with increasing concentrations of cadmium chloride were conducted on haemocytes. Results after 4 and 24 h of incubation at 20°C are reported in Table 1. Results showed no significant effect of cadmium after 4 h and 24 h.

In presence of methylmercury, haemocyte mortalities ranged from 18% ($2 \cdot 10^{-10}$ M) to 31% ($2 \cdot 10^{-6}$ M) at 24 h (Figure 1a). However, these differences were not statistically significant. With mercury chloride, a dose-dependent increase of mortality was reported after 4 and 24 h of contact : haemocytes presented 50% and 80% of mortality at 4 and 24 h respectively at $2 \cdot 10^{-4}$ M (Figure 1b).

Pollutant effects on haemocyte cellular activities

Esterase, peroxidase, aminopeptidase and phagocytosis activities were evaluated after 4 and 24 h of contact with increasing concentrations of mercury chloride. Mercury presented a significant effect on percentages of aminopeptidase (AP) positive cells after 24 h incubation. Percentages of haemocytes presenting an AP activity were important (75-90%) after 4 h incubation for all concentrations tested (Figure 2a). Although no AP activity was detected in control haemocytes after 24 h incubation (<5%), percentages of AP positive cells remained important (79%) in presence of mercury (Figure 2b). The effect of mercury chloride was dose-dependent and statistically significant. However mercury had no significant effect on esterase, peroxidase and phagocytosis activities (Figures 2a, 2b).

Experiments were also conducted on haemocyte in presence of enzyme inhibitors (sodium azide and bestatin) in the absence of pollutant in order to control labelling specificity. Addition of sodium azide demonstrated a dose dependent reduction of peroxidase activity (Figure 3a). Addition of bestatin showed a dose-dependent decrease of aminopeptidase activity (Figure 3b).

Pollutant effects on PO-like activity

The effect of mercury was also tested on plasmatic PO-like activity. The optical density was different in controls (OD = 0.6) and in acellular fraction incubated in presence of mercury (OD = 0.03) after 21 h incubation (Figure 4). PO-like activity decreased after 3 h incubation for both mercury concentrations tested. Statistical analysis confirmed the effect of mercury on PO-like activity detection.

Interactions between media and mercury on haemocyte mortality

Experiments including different maintenance conditions of haemocytes in presence of mercury chloride were conducted. After 4 h of incubation at 20°C (Figure 5a), mercury induced a statistically significant and dose-dependent increasing mortality of haemocytes maintained in haemolymph with or without antibiotics. Cells maintained in FSW presented the highest mortality (50% for $2 \cdot 10^{-4}$ M), but not in a dose dependent way. Results after 24 h of contact with mercury chloride at 20°C showed increasing of mortality but not in a dose-dependent way if the highest concentration of mercury ($2 \cdot 10^{-4}$ M) was included (Figure 5b). For cells incubated without antibiotics, mortality of the control was elevated (20% in FSW and 36% in haemolymph).

IV. DISCUSSION

Inhibition of enzymatic activities detected by flow cytometry

Experiments involving enzyme inhibitors were carried out in order to control the specificity of haemocyte labelling, since the kits used were first developed for mammal cells. Addition of sodium azide demonstrated a significant decrease of peroxidase activity in oyster haemocytes. Sodium azide is known to be a strong inhibitor of oxidative burst which involves peroxidase and particularly myeloperoxidase (28, 29, 30, 31). Addition of bestatin resulted in a dose-dependent inhibition of the haemocyte labelling. Bestatin is known as a specific inhibitor of aminopeptidase activity in mammals (32, 33, 34). These results indicate that the commercial kits may be used to detect specifically enzymes in oyster haemocytes.

The observation of haemocytes by epifluorescence microscopy assessed the validity of flow cytometry. After 1 h of incubation with beads, haemocytes presented ingested fluorescent beads, using an epifluorescent microscope as previously described in *Ostrea edulis* (35).

Pollutant effects on haemocytes

Haemocytes are known for their properties of spontaneous aggregation. This phenomenon appears during cell collection and must be integrated in cell analysis. No anti-aggregant solution was used during haemocyte collection because such solutions may inhibit haemocyte activities. Alsever solution, an anti-aggregant solution, decreases oxygen metabolite production in *Mytilus galloprovincialis* Lk (36). Moreover, aggregation of *Crassostrea gigas* haemocytes is strongly reduced at 4°C (24). Another study indicates that the maintenance of haemocytes on ice prevents their aggregation (37).

The volumes of pollutants finally added were selected so as not to modify osmolarity (10 $\mu\text{L.mL}^{-1}$ of haemolymph). First solutions of pollutants were prepared at high concentrations in order to obtain high final dilution factors of the solvent (between 100 and 10 000 for the different pollutants). High pollutant concentrations were used in order to investigate acute toxicity on oyster haemocytes. Indeed, no bivalve cell line is available and no culture system permits the maintenance of haemocytes *in vitro* for long periods after collection. Furthermore, since bivalves can accumulate contaminants in their tissues, the concentrations used on cells are likely to be similar to those existing in animals (25, 38, 39, 40, 41, 42, 43).

Cadmium induced no effect on haemocyte mortality. Literature reports contrasting observations : after 24 h of exposition with 10^{-5} to 2.10^{-3} M of CdCl_2 , haemocytes of *Mytilus galloprovincialis* presented a dose-dependent increase of mortality (44). Another study showed influence of Cd on *Mya arenaria* haemocytes for 10^{-4} and 10^{-3} M (1). However, these concentrations are higher than those used in the present study. At lowest concentrations, Cd was found to be not immunotoxic since it did not inhibit phagocytosis activity of *Tapes philippinarum* haemocytes (45). In the present study, cadmium was not able to kill haemocytes from *C. gigas* at concentrations ranging from 3.10^{-11} to 3.10^{-4} M. This pollutant did not demonstrate an immunotoxic potential by killing haemocytes.

Mercury is known for its high toxicity and its bioaccumulation in various organisms which is a significant cause of mortality of aquatic species (38). Methylmercury is supposed to be the most toxic form of mercury : the methyl group facilitate penetration into cells and binding to proteins. The present study reports no significant variation of mortality of haemocytes. Literature reports increasing of mortality on haemocytes of *M. edulis* and *Mactromeris polynyma* for 10^{-4} M and an earlier effect on phagocytosis (10^{-7} M) (1, 46). These concentrations are higher than those reported here. In our experimental conditions, methylmercury was not immunotoxic for haemocytes, like cadmium.

Mercury chloride is reported to be less toxic than methylmercury. The employed concentrations in this study were thus higher. Increasing concentrations (2.10^{-6} , 2.10^{-5} and 2.10^{-4} M) caused oyster haemocyte mortality after 4 h incubation. Such a rapid effect was previously reported in Eastern oyster, *C. virginica*, haemocytes (9). Haemocyte mortality increased in a dose-dependent way after 2 h of contact with 2.10^{-6} , 4.10^{-6} and 2.10^{-5} M of HgCl_2 (9). *In vitro* studies showed an effect of mercury at higher concentrations than those used in this study : increasing mortality was detected on haemocytes of *Mya arenaria* L., *Mya truncata*, *M. edulis* and *Mactromeris polynyma* at 10^{-3} M and higher concentrations (1, 46).

Some cellular activities were investigated in the presence of mercury chloride. An effect of mercury on percentages of AP positive cells was noticed : after 24 h of incubation, the percentage of AP positive cells increased following increasing mercury concentrations. Two hypothesis can be formulated to explain this result: (i) mercury acts indirectly on haemocytes by limiting bacterial development in the medium (47, 48), thus preserving cell

activities; or (ii) conservation of AP positive cells is a real cellular reaction induced by mercury. Aminopeptidases are hydrolytic enzymes already described in the haemolymph of *Biomphalaria glabrata* and *Crassostrea virginica* (49). Some of them are present in granules of granulocytes, are released into serum by degranulation (50) and act in post-phagocytosis reactions (51). These enzymes degrade surface proteins of parasites (50). The AP activity is also well known in vertebrates : they play a key role in the generation of MHC presented peptides (52, 53).

Mercury may cause a modulation of some haemocyte activities following its concentration. It has been proved to modify cellular activity, particularly phagocytosis. A previous *in vitro* study (9) reported an increasing effect of mercury on phagocytosis at 4.10^{-7} M, and a dose-dependent decrease for 2.10^{-6} , 4.10^{-6} and 2.10^{-5} M. Mercury also caused a decrease of phagocytosis for 10^{-6} M on haemocytes of *Mya arenaria* L., *Mya truncata*, *M. edulis* and *Mactromeris polynyma* (1, 46). The present work did not report effects of mercury neither on phagocytosis, nor on esterase and peroxidase activities. These three parameters are known to be related since phagocytosis is accompanied by the release of a variety of cytotoxic agents (reactive oxygen species and peroxidases which are involved in the oxidative burst) and lysosomal enzymes including esterases (54, 55, 56, 57).

Concerning phenoloxidase (PO)-like activity, mercury completely inhibited the transformation of L-Dopa in haemolymph. The maximum PO-like activity was detected after 21 h incubation in oysters, which suggests the presence of an inactive form of PO-like enzyme as it was already demonstrated in *Mytilus edulis* (58). Effect of pollutants on PO-like activity was studied with copper which is known to reduce this activity in *Mytilus edulis* L. (59). Polychlorinated biphenyls decreased PO-like activity in gray shrimp (*Crangon crangon* L.) after a five day exposure (60). On the contrary, PO-like activity was found to increase in presence of fluoranthene in *Mytilus edulis* (61). Response may change regarding the pollutant. In this work, mercury acts rapidly on PO-like activity. Its effect is dose-dependent and time-dependent.

Interactions between media and mercury on haemocyte mortality

The use of different incubation conditions of cells confirms that cell centrifugation may be a factor of stress and decreased cell viability as compared with cells incubated in

haemolymph. For this reason, the effects of mercury are detectable at lower concentrations in FSW : cells may indeed be more sensitive to a pollutant when they are stressed.

The condition leading to the lowest mortality without pollutant seems to be haemolymph supplied with antibiotics. Antibiotic supplementation may reduce bacterial development, whereas haemolymph certainly furnishes active molecules involved in cell survival. RPMI, NaCl supplied RPMI, and haemolymph have been tested in a previous study (46) ; haemolymph appeared to be the only medium in which cells conserved phagocytosis activity. These results allowed to define haemolymph supplied with antibiotics as a medium of interest for *in vitro* toxicity studies.

Cadmium appears as a non-immunotoxic substance for oyster haemocytes. On the contrary, mercury is an active pollutant. It causes cell death and haemocyte activity modulation. Results were confirmed by experiments undertaken by flow cytometry and by spectrophotometry. Mercury seems to be a molecule of interest for the study of *in vitro* immunotoxicity. It causes effects in a short period of time. *In vitro* experiments may be used as a tool to determine mechanisms of pollutant immunotoxicity. This approach may help to understand some responses showed by *in vivo* and *in situ* studies and to confirm the hazardous potential of certain molecules as compared to others. However, in our experiment, pollutants were added separately to haemocytes, whereas animals in natural environments are submitted to mixed pollutants. It would thus be interesting to conduct *in vitro* experiments using mixed heavy metals. Antagonist or additive effects may exist: for instance, the presence of zinc or cadmium may decrease the toxic effects of mercury *in vivo* (62, 63).

High concentrations of mercury caused cell death, but little effect on other haemocyte parameters. This result can be related to the analysis method since parameters were only measured on surviving cells. It may be hypothesised that mercury has a direct action by inducing cell death. Such a mode of action would result in a decrease of haemocyte number, and thus a reduction of the capacity of defence. PO-like activity decreases also in presence of mercury. Reports have been made on the possible existence of a relationship between pollutants and diseases. Indeed, chronic exposure of *Crassostrea virginica* to TBT increased progression of *Perkinsus marinus* infection (64). Thus, we may suspect that in areas contaminated with mercury, oyster defence capacities may be reduced, which could enhance the sensitivity of animals to infectious diseases.

Acknowledgments

P. Gouletquer is acknowledged for allowing the work at the IFREMER station in La Tremblade (Charente-Maritime, France). This research was supported in part by the Regional Shellfish Farming Section. Thanks to Valerie Barbosa Solomieu for her reading of this document. Drs Eric Thiebaut (Université de Paris VI) and Patrick Soletchnik (LCPC, IFREMER La Tremblade) are thanked for their help in statistical treatment.

Tableau 1 : Haemocyte mortality tested by flow cytometry with increasing concentrations of cadmium *in vitro* ($0-3.10^{-11}-3.10^{-10}-3.10^{-9}-3.10^{-8}-3.10^{-7}-3.10^{-6}-3.10^{-5}-3.10^{-4}$ M) after 4 and 24 h incubation at 20°C. Values are averages of two replicates.

| | Control | 3.10-11 M | 3.10-10 M | 3.10-9 M | 3.10-8 M | 3.10-7 M | 3.10-6 M | 3.10-5 M | 3.10-4 M |
|-----|---------|-----------|-----------|----------|----------|----------|----------|----------|----------|
| 4h | 9,3 | 9,4 | 9,0 | 10,7 | 9,7 | 9,2 | 9,6 | 10,5 | 10,7 |
| 24h | 12,5 | 13,5 | 20,1 | 19,7 | 31,8 | 23,9 | 18,4 | 30,8 | 17,0 |

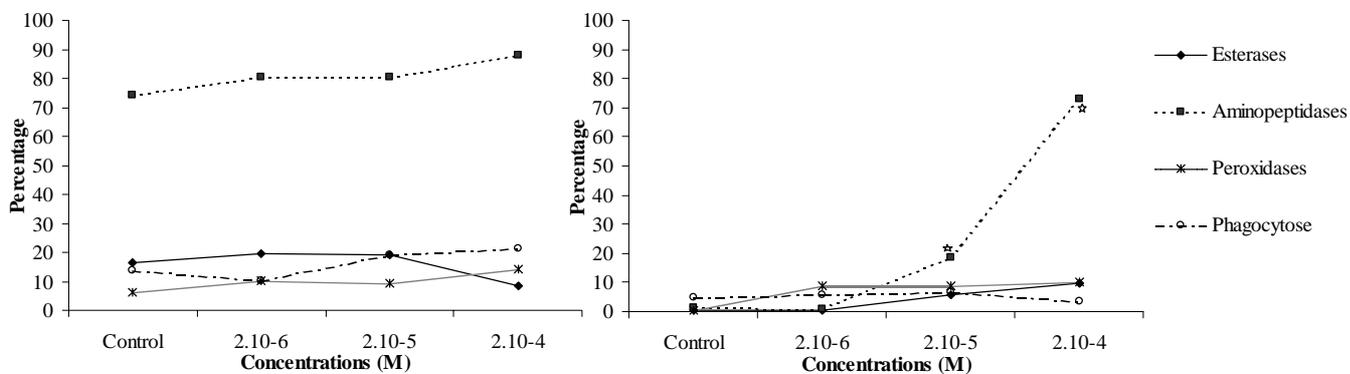

Figure 1 : Haemocyte mortality tested by flow cytometry with increasing concentrations of mercury *in vitro* after 4 and 24 h incubation at 20°C. Values are averages of three replicates

1.a : Contact with methylmercury ($0-2.10^{-11}-2.10^{-10}-4.10^{-10}-2.10^{-9}-2.10^{-8}-2.10^{-7}-4.10^{-7}-2.10^{-6}$ M).

1.b : Contact with mercury chloride ($0-2.10^{-6}-2.10^{-5}-2.10^{-4}$ M). $\Pi=$ statistical difference for $p=0.05$.

Figure 2 : Esterase, peroxidase, aminopeptidase and phagocytosis activity tested by flow cytometry with increasing concentrations of mercury chloride *in vitro* ($0-2.10^{-6}-2.10^{-5}-2.10^{-4}$ M) at 20°C. Values are averages of three replicates.

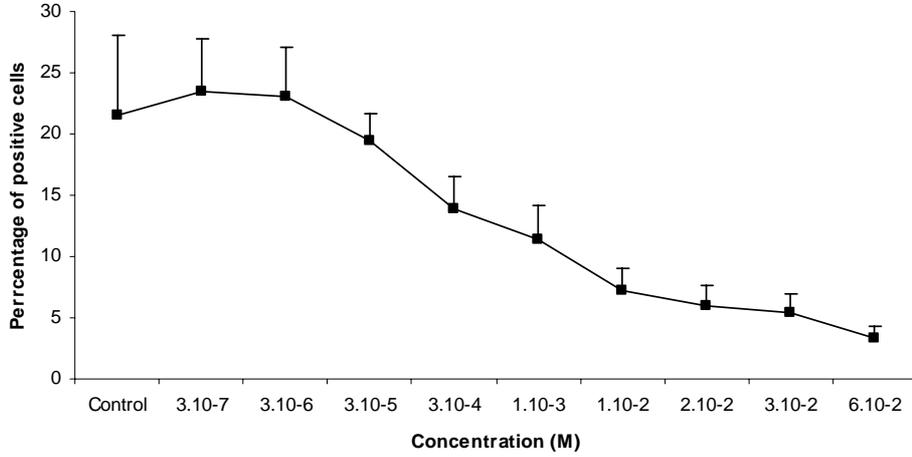

2.a : Results after 4 h of incubation.

2.b : Results after 24 h of incubation.

Π= statistical difference for $p=0.05$.

Figure 3 : Evaluation of enzymatic activities with specific inhibitors.

3.a : peroxidase positive cells percentage tested by flow cytometry with increasing concentrations of sodium azide *in vitro* ($0-3.10^{-7}-3.10^{-6}-3.10^{-5}-3.10^{-4}-10^{-3}-10^{-2}-2.10^{-2}-3.10^{-2}-6.10^{-2}$ M). Values are averages of three replicates.

3.b : aminopeptidase positive cells percentage tested by flow cytometry with increasing concentrations of bestatin *in vitro* ($0-5.10^{-2}-5.10^{-1}$ M). Values are averages of two replicates.

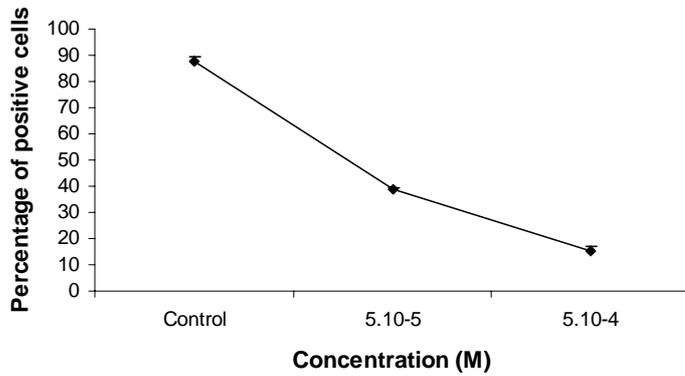

Figure 4 : PO-like activity tested by spectrophotometry with two concentrations of mercury chloride *in vitro* ($0-2.10^{-6}-2.10^{-5}$ M) after 21 h incubation. Values are averages of two replicates.

Π= statistical difference for $p=0.05$.

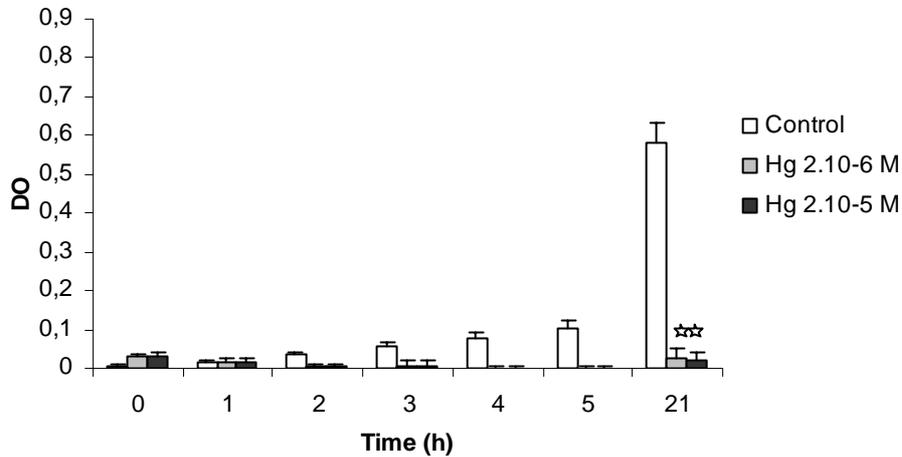

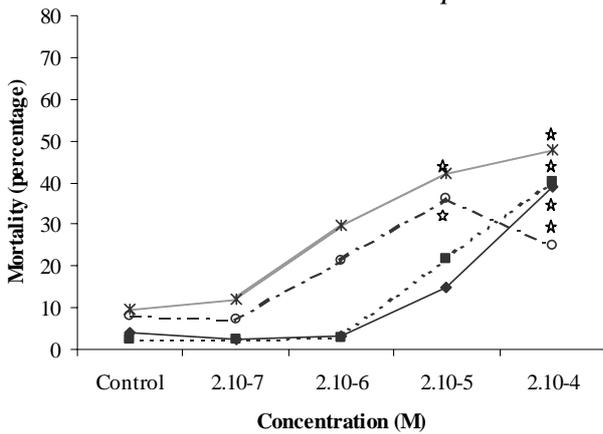

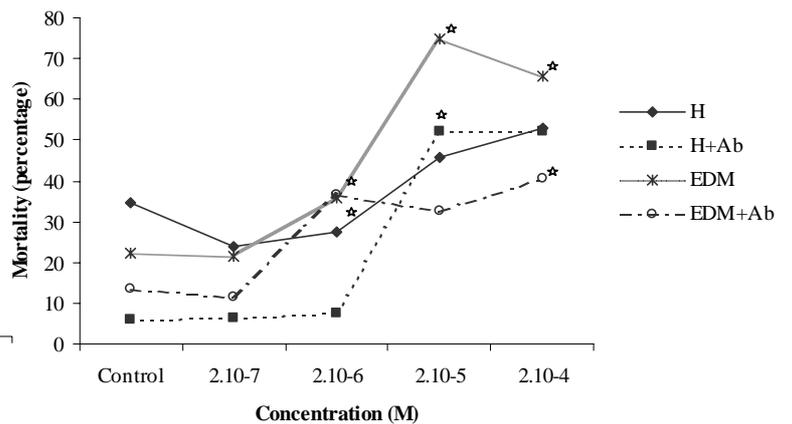

Figure 5 : Haemocyte mortality tested by flow cytometry with increasing concentrations of mercury chloride *in vitro* ($0-2.10^{-7}-2.10^{-6}-2.10^{-5}-2.10^{-4}$ M) after incubation at 20°C with different treatments. Values are averages of three replicates.

Π= statistical difference for $p=0.1$

5.a : Results after 4 h of incubation.

5.b : Results after 24 h of incubation.
