**SUMMARY:** Several works have demonstrated trends in the distribution of fish species relative to global warming. This study investigated whether similar trends have occurred for selected flatfish species on the continental shelf of the Bay of Biscay. These species were used as indicators and changes in their populations were studied in a coastal nursery ground where flatfish juveniles are concentrated as well as on the entire shelf. Previous studies analysing changes in sea surface temperature for the continental shelf indicate that winter warming occurred in the 1980s and 1990s. Sixteen autumn cruises conducted since 1981 in the Bay of Vilaine nursery area and 11 autumn cruises since 1987 over the entire shelf provided data on a nearly annual basis for the abundance of benthic fish. The four most common flatfish species were selected and their occurrence and yearly abundance were analysed with regard to specific biogeographic ranges and climate change. Similar results were obtained for juveniles on a nursery scale and for all age groups on the entire shelf. Although sole (*Solea solea*) showed irregular yearly variations, northern winter spawners such as plaice (*Pleuronectes platessa*) and dab (*Limanda limanda*) exhibited significantly high abundance during the 1980s, followed by a continuing low level and ultimately zero catches. On the other hand, the wedge sole (*Dicologlossa cuneata*), a southern summer spawner, showed an increasing trend in the late 1990s.

**RESUMEN:** CAMBIOS EN LA APARICIÓN Y ABUNDANCIA DE ESPECIES DE PECES PLANOS DURANTE UN PERIODO DE 20 AÑOS EN UN ÁREA DE CRÍA COSTERA (BAHÍA DE VILAINE) Y EN LA PLATAFORMA CONTINENTAL ORIENTAL DEL GOLFO DE VIZCAYA. – Diversos trabajos han demostrado tendencias en la distribución de especies de peces relacionadas con el calentamiento global. Este estudio se investigó si han ocurrido tendencias similares en especies seleccionadas de peces planos en la plataforma continental del Golfo de Vizcaya. Esas especies fueron usadas como indicadores y los cambios en sus poblaciones fueron analizados tanto en un área costera de concentración de juveniles como en toda la plataforma. Estudios previos de los cambios en la temperatura superficial del mar en la plataforma continental, indican la ocurrencia de periodos de calentamiento de invierno en los años 1980s y 1990s. 16 campañas de otoño realizadas desde 1981 en el área de crecimiento de la Bahía de Vilaine y 11 campañas de otoño efectuadas desde 1987 en toda la plataforma continental proporcionaron datos en una base casi anual de la abundancia de peces bentónicos. Se seleccionaron las cuatro especies de peces planos más comunes y su presencia y abundancia anual fueron analizadas con respecto a sus rangos biogeográficos específicos y al cambio climático. Se obtuvieron resultados similares para los juveniles en su área de crecimiento y para todos los grupos de edad a escala de toda la plataforma continental. Aunque el lenguado (*Solea solea*) mostró variaciones anuales irregulares, la solla (*Pleuronectes platessa*) y la limanda (*Limanda limanda*) que se reproducen en invierno mostraron una abundancia significativamente más alta durante los 1980s, seguida de una disminución continua y por último capturas nulas. Por el contrario, el lenguadillo (*Dicologlossa cuneata*), que se reproduce en el sur durante el verano, mostró una tendencia al incremento a finales de los 1990s.

**Palabras clave:** peces planos, distribución espacial, calentamiento del océano, Golfo de Vizcaya.

## INTRODUCTION

Demersal fish assemblages on the continental shelf of the Bay of Biscay have been analysed from catches of professional trawlers (1979-1993) by Poulard and Léauté (2002) and scientific survey data (1987-2000) by Poulard *et al.* (2003). Both studies indicate the relative stability of fish communities in the medium term. However, marine communities exhibit long term changes in the context of a persistent increase of the ocean heat: in coastal systems, seagrasses have been and will continue to be modified (Short and Neckles, 1999), while the distribution of open ocean planktonic communities has exhibited northward shifts (Beaugrand *et al.*, 2002).

Climatic changes affect marine fish to differing degrees. Rare warm water species have been recorded along the Cornish coast of the UK by Stebbing *et al.* (2002), who reported an increase in such observations after 1985. On a wider geographical and temporal scale, Quéro *et al.* (1998) have noted a northward extension of “rare” tropical fishes along the continental slope since 1963, which they attribute to the warming of the European Atlantic waters. As the waters of the southern Bay of Biscay show a significant increase in the sea surface temperature (a mean rise of 1.4°C for the period 1972-1993 according to Koutsikopoulos *et al.* (1998), progressive changes may be expected in the distribution of demersal fish in the shallow part of the continental shelf. The present study provides a preliminary analysis of surface temperature in the northern (and broader) part of the Bay of Biscay (Fig. 1) and then investigates changes in the specific distribution and abundance of four selected flatfishes.

Two data sources were used: (i) coastal nursery ground surveys carried out in the Bay of Vilaine over a 20-year period (Désaunay *et al.*, 1981, Le Pape *et al.*, 2003), which show a temporal trend in flatfish juvenile abundance; and (ii) groundfish surveys conducted by Ifremer on the eastern continental shelf of the Bay of Biscay since 1987 (Poulard *et al.*, 2003), which provide species abundance indices.

## MATERIAL AND METHODS

### Sea surface temperature (SST) in the northern Bay of Biscay for the two last decades

Mean SST values, computed per period of 10 days, were extracted from the Météo-France data

base from 1981 to 1998 for an area located between 46°N and 47°20'N, and 2°W and 3°W. Three different values were analysed: annual mean SST and minimum and maximum annual values.

### Selection of species

Data were available over the whole period for four species: the common sole (*Solea solea*, Linné, 1758), the plaice (*Pleuronectes platessa*, Linné, 1758), the dab (*Limanda limanda*, Linné, 1758) and the wedge sole (*Dicologlossa cuneata*, Moreau 1881). Other flatfishes such as solenette, scaldfish, flounder, brill and turbot were too scarce to provide reliable abundance indices.

According to the general descriptions by Wheeler (1978) and Whitehead *et al.* (1986), the Bay of Biscay corresponds roughly to the centre of geographical distribution of common sole and plaice, but marks the southern limit of cold-temperate species such as dab and the northern limit for the warm-temperate wedge sole.

However, these distributions are rather theoretical or based on old data. Plaice, for example, has never been caught during bottom-trawl surveys in recent years along the northwestern Mediterranean (Bertrand, pers. com., from MEDITS cruises), although Fischer *et al.* (1987) report its presence along the Mediterranean coast of Spain. Moreover, plaice was never found in the Sado estuary (Portugal) by Cabral (2000), who carried out an extensive inventory of the flatfish community and identified three tropical flatfishes for the first time in those waters. Hence, the Bay of Biscay now seems to be closer to the southern limit than to the centre of plaice distribution.

### Chronology and sampling protocol for the surveys in the Bay of Vilaine

This area of 330 km<sup>2</sup>, covered with soft sediments, extends from the estuary of the Vilaine river to a depth of 35 m (Fig. 1). Specific abundance estimates were extracted from a database collecting the results of almost yearly beam-trawl surveys performed in the Bay of Vilaine. Sixteen autumn cruises were carried out from 1981 to 2001 (all years except 1991, 1994, 1995, 1998 and 1999). The gear used, a 3-metre beam trawl without a chain ahead of the foot rope and with a 20-mm stretched mesh at the codend, was hauled at 2.5

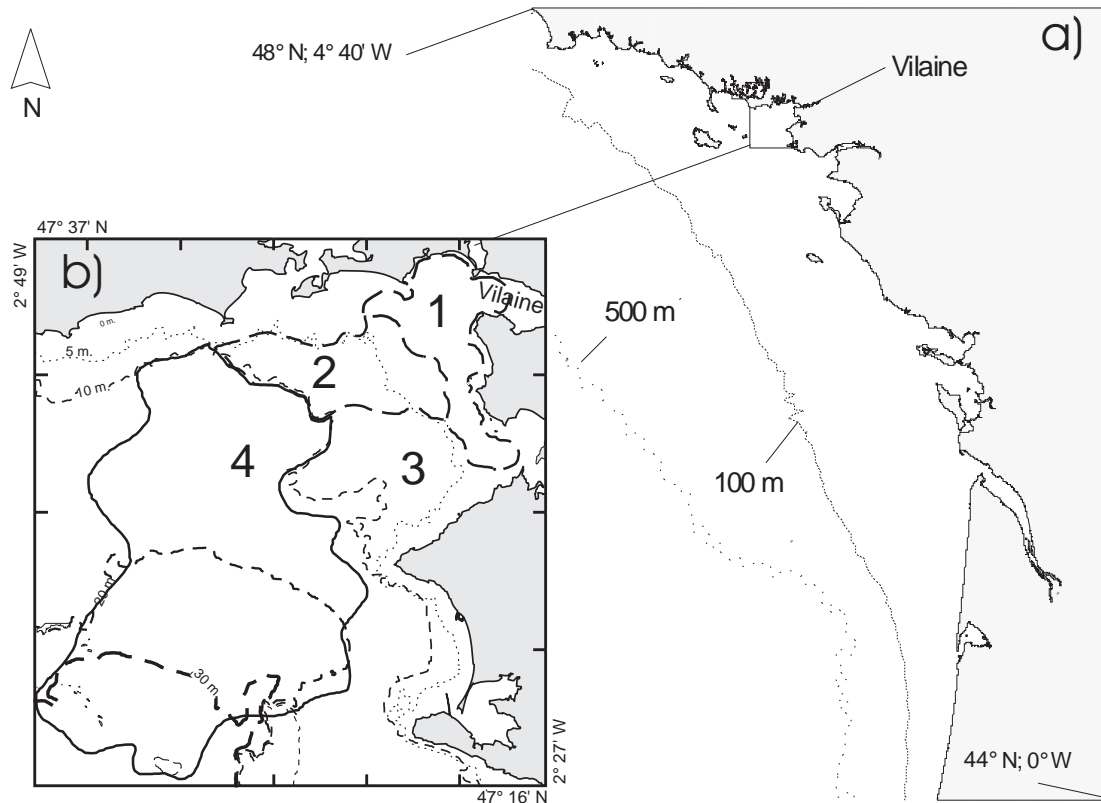

FIG. 1. – a, Map of the Bay of Biscay, showing the coastline, the 100 and 500 m isobaths, and the location of the bay of Vilaine; b, Map of the Bay of Vilaine, showing the coastline, the 5, 10, 20 and 30 m isobaths and the limits of the four sampling strata

knots for 20 min. An average of 45 trawl stations were included in each cruise. The sampling protocol relied upon a 4-stratum scheme (Fig. 1), in which strata were identified by depth range and sediment type (Le Pape *et al.*, 2003).

As the bias due to selectivity with a 20-mm mesh size is negligible in autumn for the 0-group of winter spawner species (size range is 7-15 cm for plaice, 6-9 cm for dab, and 6-14 cm for sole); these 0-group abundances were estimated without correction. For wedge sole, which spawns in summer, most of 0-group fish under 9 cm in length escaped through the codend, so this species is better estimated by the 1+2-groups (size range: 12 to 24 cm). Separation into age groups was done from the size composition of the catch, either by a hiatus between 0-group and 1-group, or by otolith examination.

The occurrence of each species was expressed as the relative number (in %) of positive hauls in a survey. Abundance estimates were based on the number of individuals caught per stratum according to Pennington and Grosslein (1977) relative to the stratified sampling scheme of the survey, i.e. estimated density for each stratum was multiplied by

area size, and the total number of individuals was estimated as the sum of these four strata.

Thus, data provide information on the success of regional spawning and colonisation of the nursery by young-of-the-year fish.

#### Data from groundfish surveys over the eastern part of the Bay of Biscay shelf

Data were collected during the eleven groundfish surveys carried out by Ifremer in the Bay of Biscay (Fig. 1) from October to December since 1987 (Amara *et al.*, 1998; ICES, 1997; Souissi *et al.*, 2001). The survey area was located between 48°30'N in the north and the northern edge of the "Gouf de Cap Breton" in the south. The sampling scheme was stratified according to latitude and depth, and a 36/47 GOV trawl with a 20 mm mesh codend liner was used. Hauls were run for 30 min, with a towing speed of 4 knots. Fishing was mainly limited to daylight hours. Catch weights and catch numbers were recorded for all species, all finfish and a selection of shellfish were measured. About 130 to 70 hauls per survey provided data on the

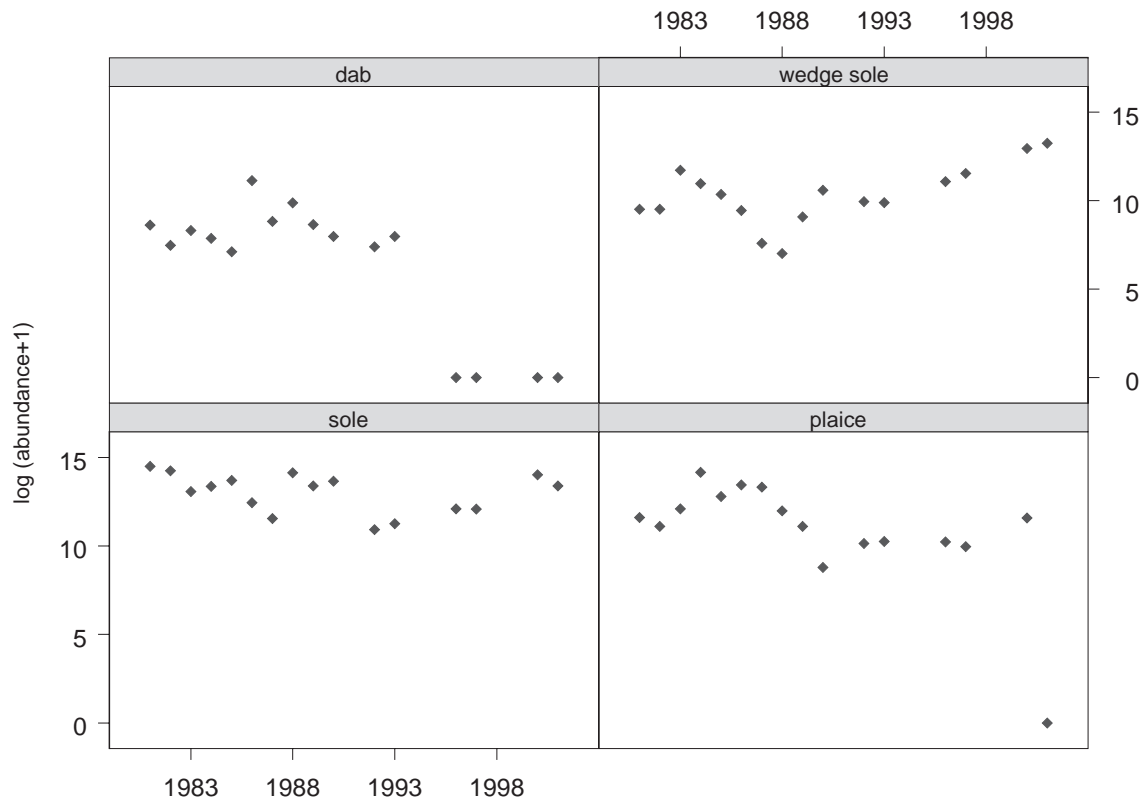

FIG. 2. – Time series of the log-transformed juvenile abundances for four flatfish species in the Bay of Vilaine nursery ground from 1981 to 2001.

occurrence and abundance of the selected species. Abundance was given by the mean number of individuals per trawl, and the occurrence of each species was expressed as the relative number (in %) of positive hauls in a survey. As age composition for the studied species was not available from this survey, all year classes were pooled.

**Data analysis**

A Kendall correlation test was used to check for correlation between the year (used as a descriptor) and the response variables (3 SST indices and 8 annual abundance indices). This non-parametric method was chosen because of the non-linear trends between the year and the studied response variables.

**RESULTS**

**Sea surface temperature trends in the northern Bay of Biscay**

Kendall correlation tests showed no trend in mean and maximum SST, but an increase in the minimum SST (positive correlation,  $\alpha = 2\%$ ) in the

northern Bay of Biscay. This indicates warming of SST on the continental shelf in winter, but no trend in SST for the other seasons.

**Yearly occurrence and abundance in the Bay of Vilaine**

The selected flatfishes were quite common at the cruise level: the common sole, plaice, dab and wedge sole were recorded respectively on 16, 15, 12 and 16 cruises out of 16. The analysis of juvenile abundance in the Bay of Vilaine nursery ground showed significant differences between species according to their biogeographical distribution (Fig. 2, Tables 1 and 3).

Northern species (plaice and dab) showed a significant decrease during the study period and totally disappeared from the area in the most recent years (the last 4 surveys for the dab and the last survey for the plaice). However, the abundance of the southern species (wedge sole) increased significantly. The Bay of Biscay is at the biogeographical centre of the sole distribution, which probably explains why recruitment fluctuations were lower than for the other species and no trend was found for juvenile abundance.

TABLE 1. – Occurrence (% of positive hauls) and abundance index (estimated in thousands of individuals for selected species in the bay of Vilaine.

	0-group sole	0-group plaice	0-group dab	1+2-groups wedge sole
<b>occurrence</b>				
1981	88.0	48.0	16.0	8.0
1982	93.3	33.3	6.7	23.3
1983	86.7	55.6	8.9	44.4

1985	55.6	25.0	2.8	27.8
1986	51.1	46.8	48.9	14.9
1987	45.8	83.3	29.2	4.2
1988	83.7	42.9	22.4	4.1
1989	56.5	34.8	8.7	21.7
1990	72.5	9.8	2.0	19.6
1992	40.0	23.6	3.6	9.1
1993	23.5	19.6	2.0	7.8
1996	42.1	26.3	0	36.8
1997	31.3	14.6	0	20.8
2000	54.5	36.4	0	72.7
2001	65.9	0	0	70.7
<b>abundance</b>				
1981	1984	110	5.5	14
1982	1535	67	1.8	14
1983	473	178	4.0	123
1984	641	1409	2.6	58
1985	895	358	1.2	31
1986	252	692	68.2	13
1987	104	611	6.8	2
1988	1366	159	19.5	1
1989	660	66	5.7	9
1990	857	7	2.9	40
1992	56	26	1.6	21
1993	77	28	2.9	20
1996	178	28	0	65
1997	177	21	0	102
2000	1227	107	0	420
2001	652	0	0	562

These results were confirmed by similar occurrence trends for these four species.

**Yearly occurrence and abundance over the Bay of Biscay shelf**

Although wedge sole was caught every year, even in low numbers, plaice was observed only on 8 cruises out of 11 and dab on 6 cruises (Table 2). Changes in occurrence and abundance (Fig. 3 and table 3) for the plaice and dab (a marked decrease in the 1990s) were contrary to those for the wedge sole (higher catches from 1997 onwards). For these three species the trends were similar to those observed for juvenile abundance in the Bay of Vilaine, confirming the decreased occurrence and abundance of northern species. No plaice were caught during the last three surveys and no dab during the last five surveys.

Figure 3 shows a clear increase of catches for the common sole. However, both data sets indicate the

same trend on a nursery ground scale for the recent period (1987 to 2000).

**DISCUSSION**

**Hydroclimatic conditions over the Bay of Biscay and local effects**

Koutsikopoulos *et al.*, (1998) described long-term warming of the sea surface in the southeastern part of the Bay of Biscay, which was mainly sig-

FIG. 3. – Time series of the log-transformed densities for four flatfish species in the Bay of Biscay from 1987 to 2000.

nificant for winter months. Planque *et al.*, (2003) confirmed a warming trend in the southern part of the Bay of Biscay (up to a 0.6°C increase per decade from 1971 to 1998), but not in the northern part. The present study also indicates that the increase in sea temperature is lower in the northern part, but that a significant warming of winter temperatures does occur there: the continental shelf of the Bay of Biscay, broader in the north, is also affected by winter warming. This is consistent with the large-scale increase in sea temperature in the northeast Atlantic, balanced by a shift toward a colder equilibrium in the sub-Arctic Gyre (Beaugrand *et al.*, (2002).

Environmental forcings on a regional scale are likely to affect fish life cycles and thus their distribution and abundance. For sole in the northern Bay of Biscay, yearly fluctuations in abundance are driven by local forcings, mainly by fluvial discharge (Le Pape *et al.*, 2003). Regional conditions such as the Poleward Current and upwelling events are responsible for the variable larval success of megrims (*Lepidorhombus whiffjagonis* and *L. boscii*) in the southern Bay of Biscay (Cantabrian Sea; Sanchez *et al.*, 2001). Moreover, demersal and benthic fish communities exhibit variations under the same

influences (Sanchez *et al.*, 2001). Thus, hydrological changes may affect populations either temporarily through recruitment processes or more permanently through adult distribution and spawning.

#### Climatic conditions versus timing of spawning and juvenile growth

Analysis of flatfish abundance showed parallel development of juveniles in the Bay of Vilaine and of the whole population studied on the continental shelf. Dab and plaice became scarce and then disappeared from catches, whereas wedge sole became more abundant and widespread.

Species such as plaice and dab, which are winter spawners at the boundary of their distribution area in the Bay of Biscay, are more sensitive to oceanic winter warming. Etel Bay (47.35°N, 03.15°W), the southernmost nursery area for dab noted in 1976 and 1977, was no longer productive in September 2002 (Désaunay, pers. comm.). Conversely, the growth and survival of early juvenile wedge sole may be favoured by winter warming in the Bay of Biscay. The common sole, which has its centre of distribution in the Bay of Biscay, is more sensitive to local habitat changes than to slight warming. As indicated

by Philippart *et al.* (1998), climatic effect may induce recruitment variations in combination with a latitudinal effect.

A comparable effect was noted by Welleman *et al.* (2001), who considered that a northward shift in spatial distribution of the common sole in the North Sea might be induced by a temperature increase. Moreover, Fox *et al.* (2000) confirmed a negative relationship between winter sea temperature and the year-class strength of plaice around the British Isles and in the North Sea. A similar relationship has been demonstrated for dab in the Bristol Channel by Henderson (1998), who showed a negative effect of temperature on 0-group growth.

Benefits and drawbacks resulting from a warming trend are species-specific. In freshwater fish, Shuter and Post (1990) showed that long periods of cold waters have a greater negative effect on smaller fish. Reciprocally, this is in accordance with the increase in smaller Soleidae (wedge sole and also the solenette *Buglossidium luteum* not described in the present study) and the decrease in large Pleuronectidae (plaice and dab) related to winter warming.

According to the concept of Pauly (1994) concerning the dominance of smaller flatfish species in tropical waters, a long-term global warming in temperate regions would probably result in higher occurrence of small flatfish species. Thus, special attention should be paid to smaller fish species such as solenette, scaldfish and topknot, which are not usually surveyed.

*Solea senegalensis*, a southern Soleidae considered as a rare fish in the Bay of Biscay by Quérou *et al.* (1980) and initially described there by Lagardère *et al.* (1979), might be expected to occur more frequently in this area. Although this species could exhibit the same northern extension as the wedge sole, its distribution is actually limited to around 46°N. Catches in our surveys remained very uncommon, perhaps because this “sole” is heavily exploited in coastal areas during the summer spawning period.

## CONCLUSION

A continuous warming trend in Bay of Biscay waters is likely to result in a long-term change in demersal fish biogeography. Beaugrand *et al.*, (2002) emphasised the serious consequences of such

a scenario for the entire marine ecosystem, particularly for fisheries. The same risk may apply to other ecosystems around the world, as described and simulated by Peterson *et al.* (2002) for Mexican faunas.

Species at the boundary of their distribution ranges need to be carefully observed through surveys conducted in coastal and shelf habitats. Wheeler (1978) has clearly warned that “there is every likelihood that extensions or modifications to the range of many species will be noted in time”. Rogers *et al.* (1998), at the end of their analysis of demersal fish communities around the UK, stressed the impact of zoogeography for the British Isles, which are at the boundary between boreal fauna and Lusitanian fauna, and expressed a need for comparable studies in more southern regions. The Bay of Biscay, an intermediate area, would seem propitious for surveying changes in the fish community.

## ACKNOWLEDGEMENTS

Sea water temperature data were provided by the French agency of meteorology Météo France. The authors wish to thank all the scientists and R.V. crews involved in the cruises. Special thanks to O. Berthelé and P. Beillois for their contribution to this paper. They are also grateful to the reviewers and to James Gray for his efficiency in improving the English text .
