#### Abstract

: This study attempts to assemble and summarize existing information in order to build a general representation of the trophic interactions within the shallow coastal ecosystem of Sri Lanka. A multispecific ecosystem-based approach on trophic relationships and their possible variations was performed using ECOPATH. Thirty-nine functional groups were considered representing all trophic levels in the food web. Time-dynamic simulation was carried out using the ECOSIM routine to evaluate the impact of the 1998 El Niño event on key functional groups. Results show that the time needed for any impacted functional group to recover to its initial abundance increased with the trophic level. Two time-series data sets derived from commercial catch and effort statistics were used for validation of ECOSIM results. The EI Niño simulation results validated by the time-series data confirmed the ability of the proposed multispecies model to describe the sudden environmental changes. Possible impacts due to increase of fishing effort were also simulated by separately considering frequently used fishing gears. The analysis revealed that small-mesh gillnet fishery operates independently from the other existing developing fisheries in the same area and can be managed accordingly. Fishing-effort simulations suggest that the increase of fishing intensity by small-mesh gillnets would contribute to the decline of small pelagic catch. This was also found to influence the overall catch. The present level of exploitation of small pelagic fishery resources does not seem sustainable.

Keywords: trophic modelling; ECOPATH; ECOSIM; trophic level; feeding relationships; fisheries management; Indian Ocean; Sri Lanka

An ecosystem-based approach to fisheries is essential for the management of exploited species and for their long term sustainability (ICES, 2000; Garcia and Cochrane, 2005). Species in an ecosystem interact biologically and are interconnected through the food webs (Pascual and Dunne, 2006). Earlier practice of treating fish stocks as independent from one another when implementing management policies is being progressively replaced by this approach (Christensen and Pauly, 1993; ICES, 2000; Garcia and Cochrane, 2005). An obvious limitation of single from multispecies fisheries management is that it does not consider a global evaluation of changes in ecosystem structure and functions related to species interactions (Mace, 2001; Pikitch et al., 2004). In the ecosystem-based fisheries management, several factors affecting resource sustainability can be integrated. Interspecies interactions within an ecosystem, impacts of the massive climatic and environmental changes and the fishing impacts are just some of the critical factors that should be integrated in the formulation of management strategies (Browman et al., 2004; Pikitch et al., 2004). Worldwide, the capacity of coastal and marine ecosystems to produce fish to serve human interest is highly degraded by over fishing, trawling and loss of nursery areas (Pauly et al., 1998; McGlade et al., 2002). In Sri Lanka, exploitation of marine resources occurs all around the coast but is mainly confined
to the narrow continental shelf, which rarely exceeds 40 km and averages around 22 km in width. The total area of the shelf is about $30000 \mathrm{~km}^{2}$, which is around $6 \%$ of the total area of the Exclusive Economic Zone (EEZ) of Sri Lanka. Coastal fishery from the seas off Sri Lanka (except in the northern and eastern areas) is a proliferating activity, which targets particularly small pelagic species. This is basically due to the remarkable productivity and high accessibility of this zone and based on the recent government incentive to develop the coastal fishery sub-sector to alleviate the increasing level of unemployment. Fishing intensity had rapidly increased due to the motorization of boats and the introduction of synthetic materials for gillnet webbing after the 1950s (Dayaratne and Sivakumaran, 1994). The fisheries sector has become adversely affected by the influx of displaced personnel due to the civil war in the North and East of the island. Unemployed people were forced to consider fishing as an occupation and resulted to the war-torn northern and the eastern parts of the island. Disputes were further aggravated during the 1990s due to the successful experimental purse seining initially practised for capturing live bait for the pole-and-line fishery.

Biodiversity of the coastal ecosystem of Sri Lanka is very rich and includes various fish populations (De Bruin et al., 1995), similarly to most other tropical marine ecosystems (Burke et al., 2001; Rocha et al., 2005). However, individual contribution of most species to the total catch is very small. The coastal fish production is mainly dominated by clupeids and other small pelagic species which are exploited by small mesh gillnets (Dayaratne and Sivakumaran, 1994).

The complex food web of this coastal ecosystem and its functioning are basically unknown. Although the biology and population dynamics of some key coastal species have been studied individually, providing estimations of population parameters, mortality, stock size and recruitment (Dayaratne, 1998; Karunasinghe and Wijeyaratne, 1998; Sanders et al., 2000, Jayawardane et al., 2002), these studies in themselves provide insufficient information to plan sustainable resource management for this ecosystem. Moreover, no attempt has been made to understand the population dynamics at an ecosystem level through trophic links.

The ECOPATH approach was designed exactly for the above purpose (Christensen and Pauly, 1993). The advantage of this kind of model is that it provides an overview of the ecosystem's trophic state
using few data requirements. Once constructed, the model can be updated and used to assess biomass response as a function of change, i.e. exploitation, climate change or degradation (Christensen et al., 2005).

Massive climatic and environmental changes due to natural phenomena such as El Niño are frequently reported from many parts of the world (Kim and Kang, 2000; Pulwarty and Melis, 2001; Cubillos and Arcos, 2002; Rodríguez-Graña and Castro, 2003; Tam et al., 2006). Some of them have affected the different functional groups of marine ecosystems (Miller and Fluharty, 1992; Souter et al., 2000; Cubillos and Arcos, 2002; Tam et al., 2006). The ability to understand how climate will change from one year to the next will lead to better management of fisheries. The resource fluctuations induced by climate variability however make complex the fisheries management. Regardless, fish populations collapse due to the inability of the fishing industry to recover from over exploitation (Forrester, 1997; http://www.csa.com/discoveryguides/archives/elnino.php). Fishery managements have to respond for minimizing those negative impacts by taking appropriate measures in resources exploitation.

The 1998 El Niño event which occurred in the Indian Ocean resulted to an elevation of sea surface temperature. Many coral reefs in the region have been affected with an extensive coral bleaching and subsequent mortality (Le Blanc, 1999). As a result, between 50 and $90 \%$ of the corals in the shallow seas off Sri Lanka were destroyed (Rajasuriya and Karunarathne, 2000). The biophysical and socioeconomic impacts on the coral reef associated fish population and dependents, particularly focusing on vulnerable groups of the coastal human population, are now being studied. However, only few studies have addressed the impact of the El Niño Southern Oscillation (ENSO) phenomenon on the coastal fish communities. Le Blanc (1999) addressed the impact of this phenomenon on tuna fisheries.

The objectives of the present study were to assemble, integrate and summarize available information to develop a comprehensive picture the Sri Lankan coastal ecosystem trophic structure and living resources exploitation in the fisheries. The recent developments of the ECOPATH mass-balance approach (Christensen and Pauly, 1992) were used as a modelling tool to develop a multispecific, trophic model for the ecosystem considered. Time-dynamic analyses using the ECOSIM routine
(Christensen et al., 2005) were also considered to evaluate possible impacts of increase in fishing effort and the severe El Niño event of 1998 on key functional groups of the ecosystem.

## 2. Materials and Methods

### 2.1. The ECOPATH model and software

### 2.1.1. Mass balance modelling

The ECOPATH software (Polovina, 1984; Christensen and Pauly, 1993; 1996; Pauly et al., 2000; Christensen et al., 2005; Pauly et al., 2000) was used to perform a mass-balance model. ECOPATH production equation for any group ' $i$ ' can be written as:

$$
\begin{equation*}
P_{i}=Y_{i}+B_{i} \bullet M 2_{i}+P_{i}\left(1-E E_{i}\right) \tag{1}
\end{equation*}
$$

where $P_{i}$ is its total production of $i, Y_{i}$ its yield or catch in weight, $B_{i}$ the biomass, $M 2_{i}$ is its total predation, $E_{i}$ the net migration (emigration - immigration), while $P_{i}\left(1-E E_{i}\right)$ is the 'other mortality'. $E E_{i}$ is the "ecotrophic efficiency", i.e., the proportion of the production of $i$ that is exported or consumed by the predators in the system.
The above equation can be re-expressed as:

$$
\begin{equation*}
B_{i} \cdot(P / B)_{i} \cdot E E_{i}=Y_{i}+\sum_{j=1}^{n} B_{j} \cdot(Q / B)_{i} \cdot D C_{j i} \tag{2}
\end{equation*}
$$

Where $(P / B)_{i}$ is the production/biomass ratio usually assumed to be equal to total mortality $Z$ defined in fisheries sciences (Allen, 1971; Lévêque et al.,1977), $(Q / B)_{i}$ is the consumption/biomass ratio, and $D C_{j i}$ is the fraction of prey $i$ in the average diet of predator $j$.

When the values for the parameters of the model are provided, ECOPATH estimates the missing parameter for each group in the model e.g. the mean annual biomass, the annual biomass production, the annual biomass consumption or ecotrophic efficiency for each of the groups in the ecosystem.

### 2.1.2. Time-dynamic simulation (ECOSIM)

Once an ECOPATH model is built, it can be used directly for simulation modelling using ECOSIM. ECOPATH mass balance results are used here as input data for this trophodynamic simulation modeling (Walters et al., 1997). The basic biomass dynamic differential equation in ECOSIM is given by:
$d B / d t=f(B)-M_{o} B_{i}-F_{i} B_{i}-\sum_{j=1}^{n} c_{i j}\left(B_{i}, B_{j}\right)$

Where $d B_{i} / d t$ represents the growth rate of group $i$ in terms of its biomass, $f(B)$ is a function of $B_{i}$ if $i$ represents primary production. In other words, $M_{0}$ is for unaccounted mortality, $F_{i}$ is fishing mortality rate and $c_{i j}\left(B_{i j}, B_{j}\right)$ is the function for predicting the amount of $i$ consumed by a predator $j$. ECOSIM solves the set of equations numerically.

### 2.2. Model construction

### 2.2.1. Boundaries for the proposed ECOPATH model

The proposed ecosystem model represents a part of the shallow coastal ecosystem of Sri Lanka in year 2000 from Chilaw up to Trincomalee (Fig.1). For the purpose of this analysis, the coastal zone has been defined to include the intertidal and subtidal areas on and above the continental shelf to about 20 km from the main shoreline (total area of around $14000 \mathrm{~km}^{2}$ ). Average Sea Surface Temperature (SST) is $28^{\circ} \mathrm{C}$.

### 2.2.2. Identification of functional groups

Fifty-eight fish species frequently reported in the fisheries data for the year 2000 were re-grouped into 29 fish functional groups (Table 1). Functional groups were categorized/grouped based on similarities in habitat, maximum body size, feeding habits, physiological behaviour and ecological distribution in order to obtain and keep homogeneous characteristics among the species within a group (Yodzis and Winemiller, 1999). For each group, whenever possible, a representative species was selected based on its importance in the fisheries and information availability. Shrimps, crabs and cephalopods which appear in the fisheries statistics were also incorporated. In addition, the following food sources for fish
were considered: bivalves, annelids, other benthic invertebrates, zooplankton, phytoplankton, phytobenthos and detritus.

As a general rule for every group, demographical parameters, diet composition, food consumption, habitat and other information were obtained from the existing literature, with preference to local and regional data. In the absence of this information, data from similar ecosystems were considered. Fishbase (www.fishbase.org) (Fröese and Pauly, 2006) has also been utilized to bridge gaps whenever possible. For non-fish groups, data sources are summarized in table 2.

### 2.2.3. Actual catch

Annual yield (Table 3) was estimated from the National Aquatic Resources Research and Development Agency of Sri Lanka (NARA) fish landings survey data and from fish landing estimates of the Ministry of Fisheries and Aquatic Resources of Sri Lanka (MFAR). Data from NARA and MFAR were used to estimate monthly catches of most small pelagic species and demersal species, respectively. For each species, annual catch is calculated as:

Total annual catch $=$ mean catch in kg per craft $\times$ mean number of crafts operated per day $\times$ mean number of fishing days per month $\times 12$ months

Annual yield for crabs is estimated based on export statistics (NARA, 2001).
The total estimated annual catch is 61,500 tons which was mainly captured by two categories of fishing gears: small mesh gillnets (i.e. mesh size 6-38 mm) and other gears for the multispecies consideration. Input catch data were standardized by area.

### 2.2.4. Basic parameters of fish

### 2.2.4.1. The Production/Biomass (P/B) ratio

For this study, we assume that $P / B$ is equal to the total instantaneous mortality, $Z$, as indicated by Allen (1971). Consequently, for commercially exploited stocks, this was calculated by obtaining the sum of the fishing ( $F$ ) and natural $(M)$ mortalities. $M$ was calculated using the empirical formula of Pauly (1980).

### 2.2.4.2. Biomass (B)

This is the total mass per functional group expressed as $\mathrm{t}_{\mathrm{km}} \mathrm{km}^{2}$. A variety of techniques have been used to estimate this parameter. Except for halfbeaks and soles, biomass per habitat area was estimated using the relationship:

$$
\begin{equation*}
B=Y / F \tag{4}
\end{equation*}
$$

where $Y$ is the annual yield and $F$ is the coefficient of the fishing mortality.
For halfbeaks and soles, biomass per habitat area was estimated using an $E E$ value of 0.5 for halfbeaks, which do not experience heavy predation, and an $E E$ value of 0.95 for soles, which are heavily predated by certain fish.

Biomasses for non-fish groups were not available except for shrimps. For shrimps, biomass was estimated from the equation (4) using the data of Jayawardane et al (2002). Phytoplankton biomass for the site considered is estimated at $2.625 \mathrm{t}_{\mathrm{km}} \mathrm{km}^{2}$ (Table 3). The Bay of Bengal large marine ecosystem (LME) has a class II productivity level, moderately productive ( $150-300 \mathrm{gC} . \mathrm{m}^{-2} . \mathrm{yr}^{-1}$ ), based on SeaWiFS global primary productivity. According to Dwivedi (1993), marshes and mangroves contribute to the overall productivity of this LME. Phytoplankton biomass is based on estimations by Pattiaratchi (2002).

### 2.2.4.3. The relative food consumption ( $Q / B$ )

For fish groups $Q / B$ ratios were computed using the predictive model of Palomares and Pauly (1998). For other groups, $Q / B$ was estimated from the empirical relationship proposed by Palomares and Pauly (1989). The aspect ratio of the caudal fin (A), indicative of metabolic activity and expressed as the ratio of the square of the height of the caudal fin and its surface area, is obtained mainly from Fishbase (www.fishbase.org)(Fröese and Pauly, 2006).

The asymptotic weight ( $W_{\infty}$ ), which is required for both models (Palomares and Pauly, 1989; 1998), was derived from the asymptotic length ( $L_{\infty}$ ). Length-weight ( $L-W$ ) relationships from Dayaratne (1998) were considered for some fish groups such as sardines; herrings; pony fishes and flying fishes,

Hirundichthys coromandelensis. For other groups, the L-W relationships were based from Fishbase (www.fishbase.org) (Fröese and Pauly, 2006).

### 2.2.5. The diet composition of every group

As indicated earlier, trophic interactions were poorly investigated in the coastal ecosystem of Sri Lanka. Only a few previous studies on feeding ecology have been carried out in this area (De Silva and Wijeyaratne, 1977 in Mohsin and Ambak, 1996). Due to the lack of available information on diet composition of groups considered, data were taken from Fishbase (www.fishbase.org) (Fröese and Pauly, 2006) and from the work of Mohsin and Ambak (1996).

When the diet of the predatory fish was not described, spatial distribution and size-range were used to predict potential prey/s (Pauly 1998; Blaber, 2000). The feeding matrix is provided in annex 1.

### 2.3. Estimating unknown parameters and evaluating the model

Basic estimations are independently made of missing parameters of ECOPATH functional groups, including estimations for trophic level ( $T L$ ) and omnivory index ( $O$ ) of each group. The group-specific omnivory index $O /$ is computed as the variance of the TLs of each predator's prey groups (Christensen and Pauly, 1993) OI varies from 0 to 1 , where a value close to 0 indicates high predatory specialization (feeding on one TL only) and 1 indicates a maximum feeding versatility on several TLs.

Following Christensen et al. (2000) the pedigree of an ECOPATH input is here understood as a coded statement that categorizes data sources based on their type and the uncertainty associated with them. Based on the options selected for each parameter for each group, a pedigree index $P$ can be calculated for the whole ecosystem as the product of all the pedigree parameter specific indices and its scale varies between 0 and 1 .

### 2.4. ECOSIM simulations

In order to assess the possibility of over-fishing, simulations using ECOSIM were carried out by increasing by two folds the fishing effort within the next ten years for small-mesh gillnets and other
gears, first separately as suggested by Walters et al. (1997), and then together. Here, the vulnerability, a parameter incorporated by Walters et al. (1997) and documented by Christensen et al. (2005) for a proper use of ECOSIM expresses the mechanism of trophic flows control in the ecosystem. It ranges from 0 (bottom up) to 1 (top down) (See Christensen et al., 2000 for more details). For preliminary investigations, an intermediate default value of 0.3 was adopted for all groups as suggested by Christensen et al. (2005). A Vulnerability Index (VI) of 0.2 as predators was only assigned to small sized fish species, for zooplankton and benthic organisms, which might be directly influenced by food availability at lower TLs.

In addition to these exercises, an attempt was made to assess the influence of an El Niño event to depict changes in primary production and fish recruitment the one that occurred in 1998. It affects the ecosystem in two ways: modifications of the recruitment of fish and decrease of the primary production. A decrease of the primary production by 2, which lasted three months (May-June), was simulated. This is a reasonable assumption, which corresponds to what happened in other marine ecosystems during a massive El Niño (http://www.csa.com/discoveryguides/archives/elnino.php). For clarity, the evolutionary trends of the biomass of few groups selected in various trophic levels (TL) were summarized. They are Phytoplankton (TL 1), Zooplankton (TL2), Herrings (TL 2.64) Sardines (TL 2.84 i.e. close to 3), Anchovies (TL 2.95 i.e. close to 3), Large tuna (TL 3.86 i.e. close to 4 ) (see below). For such a simulation, ECOSIM requires the fishing activity to remain constant.

### 2.5. ECOSIM simulation on fishing effort impacts

Two time series derived from commercial catch and effort statistics, obtained before, during and after the EI Niño were used for validation of ECOSIM results. Average monthly catch rates of Herring (catch in kg boat ${ }^{-1}$ day ${ }^{-1}$ ) derived from the fisheries statistics collected from west to east of the ecosystem for the Fibber Reinforced Plastic (FRP) boats during the period January 1998 - December 2001 were plotted to observe their trends in abundance. It should be noted that Amblygaster sirm (the representative species of the ECOPATH group Herring) is the key target species for this coastal vessel. Moreover, the catch rates for the ECOPATH group of large tunas and king fish obtained from January 1998 to December 2003 for a special category of coastal vessels (day boats, 3.5 tons with inboard engine) from the west part of the ecosystem were also plotted. It should be noted that species
represented by the ECOPATH group of large tunas and king fish are considerably exploited by these vessels. Moving average tool of Microsoft Excel software was employed to obtain smooth plots for monthly catch rates. For the validation of ECOSIM results, it was assumed that the catch rates derived from commercial fisheries statistics reflect the species abundance (Bellido et al., 2001; Haputhantri and Jayawardena, 2006).

## 3. Results

An estimated pedigree index of 0.587 conformed to the lower limit of overall quality of an Ecopath model as discussed by Christensen et al. (2005).

### 3.1. Basic estimations

The basic inputs and estimated parameters are presented in Table 3. The estimated total fish biomass was $5.101 \mathrm{t} \mathrm{km}^{-2}$ year $^{-1}$. EEs computed for phytoplankton and detritus were very low.

Assuming that zooplankton is distributed homogeneously within the first 50 meters of the water column, $0.041 \mathrm{~g} \mathrm{fw} . \mathrm{m}^{-3}$, it should be noted that the volumetric density of zooplankton is very low and this value appears to be close to several values available in Christensen and Pauly (1993).

Higher TLs (more than 3.6) were estimated for tunas and barracudas (Table 3). Important groups for fisheries belong between TL2 and TL3, mainly small-sized species which mostly feed on zooplankton and benthic organisms even as juveniles.

The data collected and assumptions made and integrated as basic inputs appear reasonable, considering the results obtained for gross efficiency (GE) of each group. In particular, GE is higher for medium and large tunas than for small ones (Table 3) which is in agreement with differential feeding habits related to maximum size. $P / Q$ for sardines is quite high due to an exceptionally high $P / B$ value, whereas it is low for large barracudas.

For several groups, the estimated EE values were higher than 0.9 (Table 3) meaning that these groups are highly predated and exploited by fisheries. A particular emphasis has to be put on the groups exploited by small mesh gillnets for which possible over fishing might be considered. The assumption of high EES for invertebrate groups appears to be appropriate as they are highly consumed as they constitute a high proportion of the diet composition of several groups (see annex 1) The computed low EEs for both phytoplankton and detritus could presumably be attributed to absent of typical primary consumers (except zooplankton) in the ecosystem. For other groups, the EE values computed by the model seem to be in an agreement with what is known both in terms of fishing pressure and possibilities of predation.

The flow diagram of the ECOPATH model is shown in Fig. 2. The ecosystem is phytoplankton-based, as $70.4 \%$ of the total food consumption comes from primary producers and only $29.6 \%$ originated from detritus, a feature of relevance in deep water bodies (Christensen and Pauly, 1993). Most primary production was consumed by the benthic organisms and zooplankton groups whereas the dominant flow to detritus (about 80\% of the total) came from primary producers (TL1).

The $O /$ of each group is also presented in Table 3. Higher $O /$ was estimated for needlefish, sea catfish and other carangids ( $0.377,0.367$ and 0.332 respectively). High O/s reflect large feeding spectrum and distribution in the ecosystem. The $\mathrm{O} /$ of shrimps and crabs were also exceptionally high. The TL of catch is 2.88 whereas the $G E$ of catch is 0.0042 .

### 3.2. Fishing effort simulation results

The outputs of the fishing effort simulations describe the situation of the ecosystem at the end of the three distinct exercises in terms of biomass and possible catch (Tables 4 to 6 ). When the small-mesh gillnets is considered, results show a biomass decline of several targeted species at various extents; for example the catch of sardines would collapse. Catches would increase to various levels for most other groups except yellowstripes, the abundance of which would decrease, most likely due to unavailability of their preys (Table 4).

Increasing the fishing effort of other gears would, most likely, not have any negative affect to the biomass of small fishes since these are mainly caught by small-mesh gillnets. Catch of some less predated fish groups are less impacted (Table 5). Moreover, the decrease in abundance of principal groups predated by tuna and barracuda increased following the stock collapse of these predators.

The increase in fishing effort for both fishing activities led to the collapse of the sardine stocks and fishery. Similar trends were observed for the three tuna groups. Herring and other clupeids stocks seem to decrease as a response to increasing fishing pressure. Thryssa and Anchovies biomass and catch would increase substantially.

An increase in fishing activity of all combined gears seemed to affect biomass of functional groups captured by the different gears. In terms of catch, small mesh-gillnet fishing seems to contribute largely to the overall decline in catch. Fishing activities by other gears increases the total catch of targeted species to about $31 \%$ (Table 5). Finally, if both fishing activities were developed simultaneously to the same extent, this would result to a decline (about 18\%) of small-mesh gillnets catches while increasing catches from other gears to about $25 \%$ (Table 6).

### 3.3. El Niño simulation results

From El Niño simulation results (Fig. 3), groups belonging to the lower TLs appear to be strongly influenced by phytoplankton abundance variations. The Zooplankton group seems immediately affected whereas other groups would affect with some delay. The delay would increase whereas the magnitude of variations decreases with increasing TL. A minimum lag time of one year was observed for trends to be stabilised. The time needed for any group to get back to its initial abundance increased with the TL. The depletion of large tuna and other predators (not displayed on Fig. 3) might have contributed to the temporary very high abundance of the clupeids, which is simulated one year after the El Niño event.

### 3.4. Model validation results

The plots of the derived monthly mean catch in kg per boat per day (CPUE) for two of the ECOPATH functional groups are shown in the Fig. 4. The figure also indicates the trends in abundance of two
groups estimated by the moving average method. The catch rates of Herring had been on a declining trend since the early months of 1999 (Fig. 4a). This was observed until end of 2000. However, this group managed to recover after 2000. The catch rates of other ECOPATH groups (large tuna and kingfish) have considerably been affected from 1999 - 2002 and gradually recovered since 2003 (Fig. 4b). Accordingly, the ECOSIM simulation results were in accordance with the actual trends in the abundance of two ECOPATH groups represented by the monthly catch rates.

## 4. Discussion

There are few pitfalls in the ECOPATH/ECOSIM approach. ECOSIM can produce misleading predictions. Erroneous predictions usually result from bad estimates or errors of omission for a few key parameters such as $B, P / B$ and $Q / B$ (Christensen et al., 2005). Moreover, incorrect assessments of predation impacts for prey that are rare in predator diets, underestimates of predation vulnerabilities and temporal variation in species-specific habitat had also been previously noted as some factors that could be influenced for final results.

The main limitation of the present model is related to the steady-state consideration, as most of the input data referred to different time periods. This ecosystem has experienced environmental fluctuations over the studied period such as the massive El Niño of 1998: Therefore, the steady-state assumption might not reflect environmental conditions closed to the reality. Moreover, the ecosystem is not completely closed and many groups such as larger fishes (tunas) are not restricted to the area.

As noted above, the major challenge for this multispecies modelling was the lack of studies on the feeding ecology of the functional groups considered. Therefore, further investigation should be carried out on this topic which should be considered as one of the key priority objective in this research area. To improve the quality of the presented model, it would therefore be necessary to improve the quality of the catch landing statistics under the above-mentioned catch monitoring programmes in order to obtain more precise estimations for a multispecies approach.

Preparation of the feeding matrix for this ECOPATH model was a difficult task since lack of previous studies on feeding ecology in relation to this ecosystem. Most of the qualitative data provided by outside studies were converted into a quantitative form for preparation of the feeding matrix. As the
model consists of many groups (39 groups), the feeding matrix contains some low percentages. In fact, these values are hard to determine from field data. This nature too might substantially influence for the final result.

The TL of catch is 2.88 due to the relative importance of intermediate TLs. The GE of catch is in agreement with earlier findings for various marine environments (Christensen and Pauly, 1993), but much lower than that observed in the San Miguel Bay, Philippines: 0.016 (Bundy and Pauly, 2001). By contrast, West African ecosystems display much lower values of the GE of the catch: less than 0.001 (Chavance et al., 2004).

The estimated total fish biomass was in fact quite low compared to some tropical littoral marine ecosystems documented in West Africa by (Palomares et al., 2003) in which estimated biomasses vary from 16.1 to $27.2 \mathrm{t} \mathrm{km}^{-2}$. The fish biomass of $5.1 \mathrm{t} \mathrm{km}^{-2}$ in the littoral waters of Sri Lanka is similar to what was computed by Christensen (1998).

For ECOSIM simulations, the choice of the values for the vulnerability parameter is very important since simulations are very sensitive to this parameter. We adopted default values which compromise between top down and bottom up regulations of the food web and might not be too far from the reality.

A further increase in the fishing effort of small-mesh gillnet fishery would seriously affect the small pelagic fish populations, mainly sardines, in terms of biomass and catches. Sardines play a vital role contributing to a significant wasp-waist control in the ecosystem. They are key species in the transferring energy from primary and secondary productions to higher TLs.

Within the ECOSIM simulations, a special attempt was made to understand the possible impacts of a sudden environmental change which could be similar to the massive El Niño event experienced in 1998. The ENSO phenomenon takes place every three to seven years and each time substantial impacts to fisheries have been observed (http://www.csa.com/discoveryguides/archives/elnino.php ; Le Blanc, 1999; Loukos et al., 2003). This phenomenon has been observed responsible for drastic reduction in the primary production due to the lack cold nutrient-rich water, which becomes limiting (Loukos et al., 2003; Roessing et al., 2004). An increase in sea surface temperature levels can alter
ecological behaviours (i.e. migration patterns, increased mortalities, change in spawning season, etc) of some groups living resources and as a consequence lead to change in ecosystem structure. This was already observed in 1997-98 in California where the distribution, abundance and catch of market squid declined (National Assessment Synthesis Team -US Global Change Research Programme, 2000; http://www.usgcrp.gov/usgcrp/Library/nationalassessment/overviewcoastal.htm) following the ENSO phenomenon. Other unusual co-occurring changes observed were widespread sea lion pup mortality in California, catches of warm-water marlin in the usually frigid waters off the Washington State and poor salmon returns in Bristol Bay, Alaska.

Roessing et al. (2004) examined the global climate change-related effects like El Niño on tropical fishes by looking at comparatively well-studied tropical coral reef ecosystems and their fish communities. They selected only the coral reef communities since previous physiological studies of other tropical fishes were found to be comparatively few. It concluded that adverse impacts on coral reef (coral bleaching and the loss of reef complexity, etc.) after severe climate-related effects could be the main causes of considerable reduction in terms of abundance and the biodiversity of several invertebrates and fishes. Coral reef communities seem to be among the first groups to show signs of such adverse effects probably due to weak trophic links even if these groups are less exploited in the fisheries (Dulvy et al. 2004). It has also been observed in some cases that increases in temperature could affect immune system function and decrease fecundity in coral reef fishes (Cubillos and Arcos, 2002).

In West Africa, the El Niño effect had completely changed the hydrology of several aquatic ecosystems. Sine Saloum, as an example, had evolved into an inverse hypersaline estuary following this event. Although it did not have considerable detrimental effects on the system's species richness, inhabiting species, mainly true estuarine, were considerably replaced by marine-estuarine species nor in some life-history traits of some fish species (Panfili et al., 2004).

Recruitment in clupeid fish species is known to be highly seasonal and variable (Karunasinghe and Wijeyaratne, 1998). Low biomass in late 1998 may be due to recruitment failure caused by El Niño. The El Niño effect in 1998 might have appeared with a certain time lag in small pelagic fishes. As
sardines and herrings have high turn-over rates (i.e., high $P / B$ ratio), the El Niño effect might have affected the landings within a short time lag.

Fish populations may need many years to recover after an ENSO phenomenon, as observed from our ECOSIM simulations. This might be due not only to the trophic link re-structuring cumulated with high fishing mortality of fished groups. Understanding such responses from different communities experiencing similar environmental changes seem to be essential to improve management decisions for sustainable utilisation of the fishery resources. But, time lag events could be tested from ECOSIM routine, which allows for the simulation of the ecosystem and therefore, provides a basis for the consideration of it as a dynamic system.

Time dynamic simulation has been an effective tool in describing the El Niño simulation results and proved useful in depicting ecosystem response to sudden environmental change. However, as noted above, there was some disagreement concerning the recovery time of affected populations between the ECOSIM predictions and the field observations. The delays in the actual recovery time of the affected populations could presumably be attributed to other factors related to significant adaptive response/s in some aggregated groups that may be "masked" due to limited information. Moreover, the catch rates derived from commercial fisheries data may not reflect correctly the abundance of the concerned fish groups.

Although it is impossible to predict the effects of global warming on the frequency of El Niño events, all indications seem to be that they are becoming stronger, more common, and are no longer disappearing completely. Some climate model experiments suggest an increase in El Niño frequency, linked to a future greenhouse warming (Timmermann et al. 1999). On the other hand, a different physical model leads to strong upwelling in the eastern equatorial Pacific that could weaken the warming there, thereby strengthen equatorial winds, causing more upwelling and a net cooling in the eastern Pacific (Cane et al. 1997).

The fishing industry of Sri Lanka was severely affected owing to the surprised tsunami disaster in $26^{\text {th }}$ December 2004. Heavy damages were especially reported from the fishing crafts operated in the
shallow coastal waters. This was greatly contributed to ease the fishing pressure on the coastal waters. Small pelagic fish landing statistics in 2005 indicated an increase trend in the catch per boat compared to previous years. On the other hand, habitat destruction by the tsunami has affected to reduce the abundance, particularly species associated with coral substrates such as butterflyfish (Chaetodontidae), gobies (Gobiidae) and wrasses (Labridae) (Rajasuriya et al., 2005; http://www.nara.ac.Ik/RAP). In addition to the above, ground level species of the food web such as phytoplankton and zooplanktons might have considerably affected during the tsunami. This would gradually affect to the higher TLs as previously observed in El Niño simulation.

The above results furthermore suggest that there is not enough evidence to accept that the current fishing practices of small pelagic species and factors other than fishery (depletion of the stocks due to other reasons) might have produced some severe changes in the fish resources availability resulting in a time limited but apparent over fishing. Therefore, more cautions should be made to keep the present levels or possibly of a lower level of exploitations of small pelagic fishes. Moreover, there are some possibilities to increase the exploitation from other gears and to target large predatory fishes, which are more abundant in deeper waters outside the present ecosystem.

## 5. Conclusion

The ECOPATH model built up to describe the trophic relationships in the coastal ecosystem of Sri Lanka helps to understand the general dynamic of this ecosystem. Moreover, quantitative and qualitative information provided by the model are in agreement with studies for similar ecosystems. This multispecific approach furthermore provides informative explanations of some incidents which took place during the past.

During a natural event such as El Niño, there is a high risk to affect the marine food web of this ecosystem. Therefore, additional care must be taken into consideration on sudden crashes of the fish populations after such an event. Recovery time of the displaced populations after a sudden environmental change could vary due to several reasons. Continuation of the exploitations furthermore by fishing during such a crucial stage might lead to a total collapse of the resources.

It was noted that there are few possibilities to increase the current exploitation of large pelagic fishery resources. However, it is advisable to provide subsidies for few fishermen who are currently engaged in coastal small scale gillnet fishery, and to direct them to the exploitation of large pelagic fish and thereby reduce the fishing pressure on small pelagic fishes. Sri Lanka has not yet been able to make effective use of the high value tuna and other resources in the deep sea areas as well as in the high seas due to the non-availability of fishing vessels with the requisite capabilities.

## Acknowledgements

We are grateful to Professor U. S. Amarasinghe of University of Kelaniya, Sri Lanka, Professor S. De Silva of Deakin University, Australia, Dr. Aruna Jayawardane and Mr. Tinil Fernando of National Aquatic Resources Research and Development Agency (NARA) of Sri Lanka for their invaluable supports to complete this study successfully. Special thank should go to Mr J.K. Rajapakshe of NARA for preparing the map of the studied ecosystem. The first author would like to thank the Asian Development Bank for granting him a scholarship to follow a PhD at École Nationale Supérieure Agronomique de Toulouse, France.

a. Fröese and Pauly (2006);
b. Estimated value with reference to $L_{\infty}$;
c. Computed value indirectly after the computation of $\mathrm{Q} / \mathrm{B}$ from the predictive model of Palomares and Pauly (1989) (see the text below) by assuming a reasonable value of gross food-conversion efficiency GE (defined by $G E=P / Q$ )) by referring to the group's diet composition $(D C)$ as suggested by Christensen and Pauly (1993).
d. Pauly (1980) (temperature for the study area was considered as $28^{\circ} \mathrm{C}$ );
e. Estimated value from the relationship $Z=F+M$;
f. Lévêque et al (1977);
g. An average of several $Z$ values for fish of the same family mainly Pampus species (Dwiponggo et al., 1986 and Dadzie et al 2003 in press);
h. Dayaratne (1998);
i. Moshin and Ambak (1996);
j. Siriwardena (1986);
k. A computed value using auximetric grid in fishbase (Fröese and Pauly, 2006);
I. A suggested value;
m. Wijeyaratne and Costa (1987);
n. An average value from two out side studies ((Abarca-Arenas and Valero-Pacheco, 1993 and Chavez et al, 1993);
o. Sivasubramaniam (1973);
p. BOBP (1987);
q. Value computed based on empirical relation of Fröese and Binohlan (2000).

Table 2. Sources of the data (mainly $P / B$ and $Q / B$ ) of non fish groups

| Group | P/B | $Q / B$ | EE |
| :---: | :---: | :---: | :---: |
| Shrimps (Penaeus indicus) | Jayawardane (2001) | A value set for P/Q $=0.20$ | Computed by ECOPATH |
| Crabs: | Abarca-Arenas and Valero-Pacheco (1993) | Arreguín-Sánchez et al. (1993a) | Value was fixed |
| Cephalopods | Christensen and Pauly (1993). | Christensen and Pauly (1993). | A fixed value |
| Molluscs | Chavez et al. (1993) | Vega-Cendejas et al. (1993). | A fixed value based on substantial predation |
| Annelids/Polychaetes | Arreguín-Sánchez et al, (1993a, b). | Arreguín-Sánchez et al. (1993a, b). | A fixed value based on substantial predation |
| Zoobenthos | Chavez et al. (1993). | Chavez et al. (1993). | A fixed value based on substantial fish and shrimp predation |
| Zooplankton | Irvine and Waya, (1999) Sarvala et al. (1999) | Irvine and Waya, (1999) Sarvala et al., (1999) ; Christensen et al. (2005) | A fixed value based on substantial juvenile fish predation |
| Phytoplankton | Pattiaratchi (2002). | --- | Biomass was available |
| Phytobenthos | Christensen and Pauly, (1993) | --- | A fixed value because of high predation |

Table 3. Input values and estimated parameters (in brackets) for the coastal ECOPATH model of Sri Lanka. TL is the trophic level, $B$ is Biomass, $P / B$ is production rate, $Q / B$ is the consumption rate, $P / Q$ is production per consumption ratio, $E E$ is the ecotrophic efficiency and $O /$ is the omnivory index.

| ECOPATH Group | TL | Catch Gillnets | $\mathrm{m}^{-2}$ year $^{-1}$ ) <br> Other gears | $\underset{\left(\mathrm{t} \mathrm{~km}^{-2}\right)}{\mathrm{B}}$ | $\begin{gathered} \text { P/B } \\ \left(\text { year }^{-1}\right) \end{gathered}$ | $\begin{gathered} \text { Q/B } \\ \left(\text { year }^{-1}\right) \end{gathered}$ | P/Q | EE | Ol |

## Figure captions

Fig. 1. A map of the studied coastal ecosystem

Fig 2. The ECOPATH model for the coastal marine ecosystem of Sri Lanka indicating relative biomass of each group and the major flows connecting them. Less important flows are omitted for clarity sake. The horizontal axis of symmetry of each box is aligned with the trophic level of this box The value of a trophic level is a fractional because it depends on the diet composition of this group and on the trophic levels of its preys (Christensen and Pauly, 1993). B : Biomass B (t km ${ }^{-2}$ ), P : Production $\left(\mathrm{t} \mathrm{km}{ }^{-2} \mathrm{yr}^{-1}\right)$, Q: Food consumption $\left(\mathrm{t} / \mathrm{km}^{2} \mathrm{yr}^{-1}\right)$. Arrows on the top of some box are actual catch. $\left(\mathrm{t} \mathrm{km}^{-2} \mathrm{yr}^{-1}\right)$.

Fig 3. A simulation of the possible effect of an El Niño event (which decreases the primary production by $50 \%$ for three months starting in May 1998) on abundance of key groups at various trophic levels. The seasonality in recruitment pattern was not considered.

Fig 4. The derived monthly mean catch rates (CPUE) for two ECOPATH functional groups: (a) Herrings (Period: January 1998 - December 2001) (b) Large tunas and kingfish (Period: January 1998 - December 2003). The trends in the CPUE obtained from the method of the moving average are also shown.
